LIST OF TABLES

<u>Table</u>		<u>Page</u>
1.	Morphometric data for Libby Reservoir.	6
2.	Current relative abundance and abundance trend from 1975 to 1987 of fish species present in Libby Reservoir.	7
3.	Lake-fill time, hydraulic-residence time, maximum drawdown, number of days held at full pool, and maximum reservoir elevation for Libby Reservoir by year from 1972 through 1987.	11
4.	Limnological sampling frequency on Libby Reservoir from 1983 through 1987.	15
5.	Mean euphotic zone depth (m) (top line) and secchi disk depth (m) (bottom line) measured in Libby Reservoir, July 1983 through December 1987. Sample size is in parenthesis.	17
6.	Primary productivity data collected from Libby Reservoir, May 1986 through January 1987. The rates are expressed as daily areal rates $(mgC/m^2/d)$.	19
7.	Mean monthly values of variable sused in regression analysis of daily areal primary productivity measured in Libby Reservoir, 1986.	21
8.	Benthic invertebrate mean densities for Libby Reservoir, 1983 through 1987.	25
9.	Mean densities of surface invertebrates for Libby Reservoir, 1983 through 1987.	33
10.	Mean biomasses of surface invertebrates for Libby Reservoir, 1983 through 1987.	38
11.	Mean density $(no./m^2/wk)$ and total number of emerging insects by year and zone in the Termile area of Libby Reservoir, June through December, 1986, and April through October, 1987.	41
12.	Monthly mean densities $(no./m^2/wk)$ of emerging dipterans captured in surface trap positioned over three elevational strata in the Termile area of Libby Reservoir, 1986 through 1987.	42
13.	Zooplankton identified in water samples collected from Libby Reservoir, Montana, 1977 and 1978 (From Irving 1987).	46

- 14. Percent composition of major zooplankton genera present 47 in Libby Reservoir, 1983 through 1987.
- 15. Non-parametric Tukey-type multiple comparisons for 50 total zooplankton, <u>Daphnia</u>, and <u>Diaptomus</u> densities by study area and year. Between-area differences are indicated by different numbers more than one number indicates similarity to both groups.
- 16. Comparison of zooplankton lengths in samples preserved 53 with formalin and with 95 percent ethanol. Samples were collected at the Tenmile area on December 18, 1986 and analyzed on March 30 and 31, 1987. Data is presented by number/mean length/standard deviation.
- 17. Average catch per net in floating gill nets set during 60 the fall in the Tenmile and Rexford areas of Libby Reservoir, 1975 through 1987.
- 18. Average catch per net in sinking gill nets set during 65 the spring the Rexford area of Libby Reservoir, 1975 through 1987.
- 19. Relative abundance of fish species captured in 74 vertical gill nets in three sampling areas in Libby Reservoir, 1983 through 1987.
- 20. Expanded estimates of kokanee numbers in Libby 77 Reservoir in August, from 1984 to 1987, as determined by hydroacoustic sampling.
- 21. Mean kokanee density in four areas of Libby Reservoir 78 during August 1984 to 1987, as determined by hydroacoustic sampling.
- 22. The calculated mean total lengths(m) at annuli for 80 rainbow trout in Libby Reservoir, 1984 through 1987.

 Measurements based on scale analysis.
- 23. Mean back-calculated lengths and monthly growth rates 82 of rainbow trout after entry into Libby Reservoir, 1985. Measurements based on otolith analysis.
- 24. The calculated mean total lengths (nun) at annuli for 84 westslope cutthroat trout in Libby Reservoir, 1984 through 1987. Measurements based on scale analysis.
- 25. The calculated mean total lengths (mn) at annuli for 85 rainbow x cutthroat trout in Libby Reservoir, 1984 through 1987. Measurements based on scale analysis.
- 26. The calculated mean total lengths (mm) at otolith 87 annuli for kokanee salmon in Libby Reservoir 1984 through 1987.

- 27. Back-calculated and back-dated lengths at first otolith 88 annulus for kokanee salmon in Libby Reservoir, 1983 through 1987.
- 28. Back-calculated lengths and mean monthly growth (mm) 89 for age 2+ kokanee salmon in Libby Reservoir, 1984 through 1987. Measurements based on otolith analysis. Sample size is in parenthesis.
- 29. The calculated mean total lengths (mm) at annuli for 91 bull trout in Libby Reservoir, 1984 through 1987.

 Measurements based on scale analysis.
- 30. The calculated mean total lengths (m) at annuli for 93 mountain whitefish in Libby Reservoir, 1984 through 1987. Measurements based on scale analysis.
- 31. Mean length at capture of 1984-1987 age classes of 95 burbot collected from Libby Reservoir, 1984 through 1987. Assignment of age classes based on otolith analysis.
- 32. The calculated mean total lengths (mm) at annuli for 96 northern squawfish in Libby Reservoir, 1984 through 1987. Measurements based on scale analysis.
- 33. The calculated mean total lengths (mm) at annuli for 98 peamouth chubs in Libby Reservoir, 1984 through 1987.

 Measurements based on scale analysis.
- 34. Number of stomachs collected for food habits analyses 100 from three areas of Libby Reservoir from 1983 through 1987. Lengths indicated for trout (<330, >330) are in millimeters.
- 35. Indices of Relative Importance for food items in the 101 stomachs of kokanee salmon in Libby Reservoir, 1983 through 1987.
- 36. Monthly Indices of Relative Importance for food item 102 in the stomachs of kokanee salmon in Libby Reservoir, 1983 through 1987.
- 37. Seasonal length group densities (no./1) and mean 104 lengths of <u>Daphnia</u> in plankton tows and ingested by knkanee by season in Libby Reservoir, 1983 through 1987. All lengths are expressed in millimeters.
- 38. Ivlev's selectivity index for size classes of <u>Daphnia</u> 105 ingested by kokanee by season in Libby Reservoir, 1983 through 1987.
- 39. Index of Relative Importance for food items in the 106 stomachs of trout species captured in Libby Reservoir, 1983 through 1987.

Indices of Relative Importance for food items in the 108 40. stomachs of trout species captured by season in Libby Reservoir, 1983 through 1987. 109 Seasonal Indices of Relative Importance for food items 41. in the stomachs of mountain whitefish in Libby Reservoir, 1983 through 1987. 110 42. Seasonal Indices of Relative Importance for food items in the stomachs of bull trout in Libby Reservoir, through 1987. 112 43. Seasonal Indices of Relative Importance for food items in the stomachs of burbot in Libby Reservoir, through 1987. 44. Indices of Relative Importance for food items in the 113 stamachs of nongame fish species in Libby Reservoir, 1983 through 1987. 114 45. Seasonal Indices of Relative Importance for food items in the stomachs of three nongame fish species in Libby Reservoir, 1983 through 1987. 116 46. Shoener index values of dietary overlap for eight of fish considered to be primarily nonpiscivorous from Libby Reservoir, 1983 through 1987. 118 47. Percent of biomass and mean lengths (mm) of zooplankton types ingested by three species of fish in Libby Reservoir, 1983 through 1987. 119 Seasonal Indices of Relative Importance for food items 48. in the stamechs of Oncorhynchus trout species and kokanee in Libby Reservoir, 1983 through 1987. 49. Shoener indes values of dietary overlap for five 121 species of fish that utilized fish as a food source Reservoir, 1983 through 1987. from 122 Percent biomass and percent frequency of occurrence of 50. individual fish species found in the diets of bull trout and burbot from Libby Reservoir, 1983 through 1987. 124 Summary of migratory trout captures in upstream and 51. downstream traps in Young Creek, 1970 through 1988.

ACKNOWLEDGEMENTS

We would like to thank all of the people who have worked on this project: Eric Bell, Bob Braund, Bob Calamusso, Les Evarts, Ken Furrow, Paul Hamlin, Nick Hetrick, Barb Kelly, John Lord, Beth Morgan, Mary Ellen Mueller, Eric Ricketts, Ron Rhew, Mark Schafer, Jose Serrano-Piche, Brad Shepard, Mark Sweeney, Steve Tralles, Kate Walker, and Chuck Weichler. They all have made valuable contributions to this effort. Brian Marotz served as co-project biologist during a portion of the project John Fraley served as project manager. John Fraley and Brian Marotz reviewed and edited the manuscript. Acknowledgement is due Gerry Oliver, of the Canadian Fish and Wildlife Branch, and Laney Hanzel, Joe Huston, Bob Domrose, Bob McFarland, and Jim Vashro of the Montana Department of Fish, Wildlife and Parks for technical assistance and information. John Priscu and Kirk Johnson of Montana State University designed the primary productivity study and conducted the study in its initial year. Dan Gustafson of Montana State University helped with some of the data sets, tables and graphics in this report. Special thanks to our office-mate, Wayne Kasworm, for his willingness to help. Dennice Hamman and Sharon Sarver typed the manuscript

EXECUTIVE SUMMARY

The Libby Reservoir study is part of the Northwest Power Planning Council's resident fish and wildlife program. The program was mandated by the Northwest Power Planning Act of1980 and is responsible for mitigating damages to the fish and wildlife resources caused by hydroelectric development in the Columbia River Basin. The major goal of this and the Hungry Horse Reservoir study is to quantify seasonal water levels needed to maintain or enhance the reservoir fishery. This study began in May, 1983, and the initial phase was completed in July, 1988.

The three study areas of Libby Reservoir are affected differently by dam operation and reservir morphology. Relative changes in water volume and surface area are greatest in the Canada and Rexford areas and least in the Tenmile area. By analyzing surface elevations, it is apparent that the reservoir was drafted less rapidly during fall prior to 1984. Since 1984, a greater percent of the annual drawdown has been shifted to fall prior to snowpack forecasts, leading to reduced flexibility indrawdownmanagement.

Oxygen and pH were not limiting for trout or salmon during the study period. Reservoir morphology, hydraulics and dam operation affect fish distribution by influencing temperature. Optimum growth conditions for kokanee existed from May to November in the Tenmile and Rexford areas and May through October in the Canada area.

The highest areal primary productivity rates were in the Tenmile and Border stations in July. Light, turbidity and temperature are the most important factors affecting primary production in the reservoir. A weak thermal structure, caused by rapid replacement of water within the reservoir, turbid spring inflows, and seasonal variations in incident solar radiation influence production.

Densities of benthic invertebrates were negatively affected by drawdown. Density significantly decreased from the permanently wetted zone to the frequently dewatered zone. The shallow and mid zones increased in density as water levels were raised. Dipterans were the predominant benthic invertebrate in all zones, but percentages decreased with depth in the reservoir.

The nearshore zone generally had greater densities and biomasses of surface macroinvertebrates than did the limnetic zone. The difference was not statistically significant due to high variances caused by patchy distribution. Lower relative densities of terrestrial insects in the Rexford area were attributed to large expanses of barren ground between the shorline vegetation and water that impeded terrestrial transport. Higher relative aquatic invertebrate densities in the Rexford area were attributed to larger areas of productive shallow water and substrate. Peaks in abundance were seasonal and related to emergence patterns of insect types.

Emergence of dipterans peaked from April through June. Emergence as no./m²/wk was greatest in the occasionally dewatered zone, followed by the frequently dewatered zone and the permanently wetted zone. Highemergenceinthe shallow zone in May could be due to transport of emerging pupae across zonal boundaries by wind or water currents, recolonization by larvae, or rapid emergence after reflooding the shallow zone during reservoir refill. Higher densities of emerging insects in the mid and shallow depths as compared to relatively low densities of benthic insects may be explained by recolonization, sampling bias, or greater productivity in shallow and mid zones than in deep zones.

The copepods <u>Diaptomus</u> and <u>Cyclops</u> madeupthe majority of the zooplankton community. <u>Daphnia</u> abundances were generally greatest in the Canada area and may be related to earlier summer warmup, decreased vertebrate predation and greater nutrient input than in the other areas. Densities of <u>Daphnia</u> < 1.5 mm were greatest and densities of <u>Daphnia</u> > 1.5 mm were least during years of high kokanee densities, suggesting a size-selective feeding behavior for kokanee. Greatest densities for all zooplankton species were foundin the upper none meters of water during spring and summer months, and maybe a response by the planktors to the shallow euphotic zone caused by turbid spring inflows.

Floating and sinking gill net trend sampling since 1975 indicates an increase in kokanee, peamouth, yellow perch, and northern squawfish populations. We observed a trend for decreased abundance in <u>Oncorhynchus</u> trout species, mountain whitefish, and redside shiner, whereas the abundances of largescale and longnose suckers, bull trout, and ling appeared to remain constant. Vertical gill net catches in the lower two study areas of the reservoir were dominated by kokanee; peamouth were dominant in the Canada area.

Hydroacoustic estimation of kokanee densities suggest a cyclic trend beginning in 1981 of a strong year class followed by two weaker year classes. This fluctuation in numbers is moderating but remains evident in the sampling. Densities of kokanee during August were generally greatest at Peck Gulch and least in the Canada area.

Analysis of otoliths and scales indicatedthatsize-at-age for Oncorhynchus trout species was related to time of emigration from their natal streams. Initial growth advantage realized by younger migrants was negated by the fourth year in the reservoir. Growth of kokanee was slowest when population densities of the previous year's kokanee were high. Greatest growth of kokanee corresponded with blooms of Daphnia. Bull trout exhibited greatest growth in the first year of reservoir life. Results differ from other studies and are possibly related to predation on kokanee, chub, sucker, trout orsomeotheravailable food source.

<u>Daphnia</u> were the most important food source for kokanee, mountain whitefish, peamouth chubs and largescale suckers during all seasons. Daphnia were also important in the diet of two size

classes of trout (< 330 mm and > 330 mm) in the winter and to a lesser extent in the fall. Competition between these species for Daphnia probably did not occur due to differences in size selection of Daphnia, habitat utilization, relative abundance, and consumptionofalternative food items. Both bull trout and burbot fed predominantly on fish, although the majority of biomass ingested by bull trout came from kokanee, largescale suckers and trout species, while largescale suckers alone accounted for the majority of biomass consumed by burbot. Further analysis will be needed if recently introduced Kamloops rainbow trout become established in the reservoir.

Catches of migratory trout in Young Creek between 1970 and 1987 reflect the effects of management activities, angler harvest, and changes in the reservoir fish community over the period. Captures increased following the removal of passage barriers, and increased again following the imprint planting of cutthroat fry in Young Creek. With the cessation of planting in 1976 and the decrease of cutthroat in the reservoir, captures in Young Creek have continually declined.

INTRODUCTION

Libby Reservoir was created under an International Columbia River Treaty between the United States and Canada for cooperative water development of the Columbia River Basin (Columbia River Treaty 1964). The authorized purpose of the dam is to provide power (91.5%), flood control (8.3%), and navigation and other benefits (0.2%).

The Pacific Northwest Power Act of 1980 recognizedpossible conflicts stemming from hydroelectric projects in the northwest and directed Bonneville Power Administration to "protect, mitigate, and enhance fish and wildlife to the extent affected by the development and operation of any hydroelectric project of the Columbia River and its tributaries..." (4(h)(10)(A)). Under the Act, the Northwest Power Planning Council was created and recommendations for a comprehensive fish and wildlife program were solicited from the region's federal, state, and tribal fish and wildlife agencies. Among Montana's recommendations was the proposal that research be initiated to quantify acceptable seasonal minimum pool elevations to maintain or enhance the existing fisheries (Graham et al. 1982).

Reservoirs are best regarded as a distinct type of freshwater ecosystem, differing from both streams and lakes (Baxter 1977). Reservoir water level management is considered to be an important tool for fisheries management (Willis 1986). Acknowledgement of the value of water level management to maintain desirable reservoir fisheries has resulted in a vast amount of research literature (see bibliographies of Triplett et al. 1980, Ploskey 1982). However, ecological approaches to understanding and predicting the potential impacts of hydrolelectric facilities are relatively new (Magnuson 1979).

An inter-disciplinary team of experts met in 1980 to discuss incorporating ecological issues in basin-level hydropower planning (Hildebrand and Goss 1981). They concluded that the capability to predict water-level changes was adequate but modeling of biological effects was inadequate. In a national survey of reservoir biologists to identify reservoir fishery research needs, better knowledge of water quality/fish interactions and the ability to predict impacts of reservoir drawdowns and/or water level fluctuations were considered highest priorities for necessary information (Hall 1985). Long-term data replicating several management and recruitment events are needed to develop these predictive models (Ploskey 1986).

Research began in May 1983 to determine how operations of Libby dam impact the reservoir fishery and to suggest ways to lessen these impacts. This study is unique in that it was designed to accomplish its goal through detailed information gathering on every trophic level in the reservoir system and integration of this information into a quantitative computer model. The specific study objectives are to:

- 1) Quantify available reservoir habitat,
- 2) Determine abundance, growth and distribution of fish within the reservoir and potential recruitment of salmonids from Libby Reservoir tributaries within the united states,
- 3) Determine abundance and availability of food organisms for fish in the reservoir,
- 4) Quantify fish use of available food items,
- 5) Develop relationships between reservoir drawdown and reservoir habitat for fish and fish food organisms, and
- 6) Estimate impacts of reservoir operation on the reservoir fishery.

DESCRIPTION OF STUDY AREA

Libby Reservoir (Lake Koocanusa))was formed by impoundment of the Kootenai River in March 1972. Libby Dam is located in Lincoln County, northwest Montana, approximately 27 km (17 mi) upstream from the town of Libby (Figure 1). The Montana portion of the reservoir is bordered mainly by the Kootenai National Forest. The majority of the private property is located near the town of Rexford.

The land adjoining the Canadian portion of the reservoir is principally owned by private citizens. A notable exception to this is the Kikomun Provincial Park which is located on the east bank of the reservoir, 10 miles south of the town of Wardner, British Columbia.

WATER QUALITY

The Kootenai River is the second largest tributary of the Columbia River, with an average annual discharge of 868 m 3 /s (30,650 cfs). Libby Reservoir and its tributaries receive runoff from 47 percent of the Kootenai River drainage basin. The reservoir has an annual average inflow of 10,615 cfs and three Canadian rivers, the Kootenai, Elk, and Bull, supply 87 percent of the inflow (Woods 1982).

Cranbrook, Fernie, and Kimberly, in British Columbia, and Eureka in Montana have contributed the major municipal point sources of water pollution. Industrial point source pollution has occurred from the Sullivan (Cominco Ltd.) lead/zinc mine and its ore concentrator on Mark Creek, Crestbrook Forest Industries Ltd. bleached kraft pulp mill at Skookumchuk, and a Cominco Ltd. phosphate fertilizer plant, also on Mark Creek near Kimberly.

By 1981, these industries had taken major steps toward pollution abatement with the installation of wastewater purifying and recycling equipment. Also, after September 1987, Cominco Ltd. closed the phosphate fertilizer plant; it is believed this will significantly reduce phosphate loadings to the St. Mary River and ultimately the Kootenai.

The drainage basin is located within the Northern Rocky Mountain physiographic province, which is characterized by north to northwest trending mountain ranges separated by straight valleys parallel to the ranges (Woods and Falter 1982). These mountains are composed of folded and faulted crystal blocks of metamorphosed sedimentary rocks of the Precambrian Belt Series.

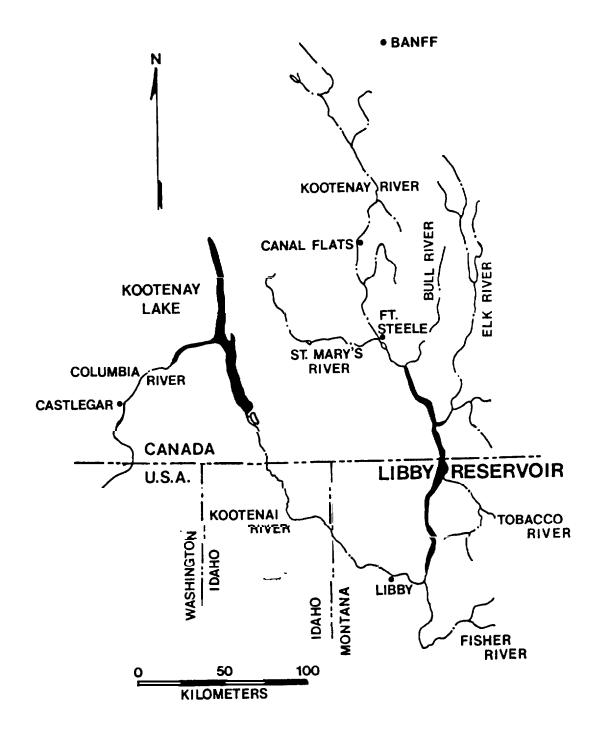

Figure 1. Map of the Kootenai River basin showing the location of Libby Reservoir (Lake Koocanusa).

MORPHOLOGY

At full pool, the reservior extends 145 km northward, with 68 km of its length located in British Columbia. Maximum volume and surface area are 7.24 km³ and 188 km², respectively (Table 1).

Libby Dam is a 113-m (370-ft) high concrete gravity structure with three types of outlets: three sluiceways, five operational penstock intakes (eight possible), and a gated spillway. A selective withdrawal system was installed at Libby Dam to allow for withdrawal of water from the reservoir ranging from the penstock invert (elevation 677 m or 2,222 ft) to within about 6 m (20 ft) of the surface at full pool (Bonde and Bush 1982). This system became operational in the spring of 1978. The dam crest is 931m long (3,055 ft) and the widths at the crestandbase are 16 m (54 ft) and 94 m (310 ft), respectively.

RESERVOIR OPERATION

Libby Reservoir is a headwater storage project operated by the Army Corps of Engineers (ACOE) as an integral part of the Columbia River Basin hydroelectric network. Reservoir elevations are managed primarily for power and flood control purposes (Storm et al. 1982). The ACOE operates Libby Reservoir to reach full pool in July, begins drafting the reservoir in September, reaches a minimum pool elevation in March, and begins refilling the reservoir in spring

FISH SPECIES

Seventeen species of fish are present in the impoundment (Table 2). Libby Reservoir currently supports an important fishery for kokanee (Oncorhynchus nerka), rainbow trout (Oncorhynchus mykiss) and westslope cutthroat (Oncorhynchus clarki) with annual fishing pressure over 500,000 hours (Chisholm and Hamlin 1987). Burbot (Lota lota) and bull trout (Salvelinus confluentus) are also important game fish, providing a significant fishery during the winter and spring months.

Table 1. Morphometric data for Libby Reservoir.

Surface elevation maximum pool minimum operational pool minimum pool(dead storage)	749.5 m (2,459 ft) 697.1 m (2,287 ft) 671.2 m (2,222 ft)
Area maximum pool minimum operational pool	188 sq. km (46,500 acres) 58.6 sq. km (14,487 acres)
Volume maximum pool minimum operational pool	7.24 km ³ (5,869,400 acre-ft) 1.10 km ³ (890,000 acre-ft)
Maximum length	145 km (90 mi)

Average annual discharge pre-dam record (1911-1972) or	12,170 cfs (Storm et al. 1982) r 11,774 cfs (our data)
post-dam record (1974-1986)	10,615 cfs

Table 2. Current relative abundance (A=abundant, C=common, R=rare) and abundance trend from 1975 to 1987 (I=increasing, S=stable, D=decreasing, U=unknown) of fish species present in Libby Reservoir.

Common Name		Relative abundance	Abundance trend
Game fish species			
Westslope cutthroat trout	Oncorhynchus clarki le	<u>wisi</u> C	D
Rainbow trout	Oncorhynchus mykiss	A	D
Bull trout	Salvelinus confluentus		S
Brook trout	Salvelinus fontinalis	R	Ū
Lake trout	Salvelinus namaycush	R	Ū
Kokanee salmon	Oncorhynchus nerka	A	Ĭ
Mountainwhitefish	Prosopium williamsoni	C	D
Burbot	Lota lota	C	Ī
Largemouth bass	Micropterus salmoides	R	U,
White sturgeon	Acipenser transmontanu	<u>s</u> R	Dª/
Nongame fish species			
Pumpkinseed	Lepomis gibbosus	R	ប
Yellow perch	Perca flavescens	С	I
Redside shiner	Richardsonius balteatu	s R	D
Peamouth	Mylocheilus caurinus	A	I
Northern squawfish	Ptychocheilus oregonen	sis A	I
Largescale sucker	Catostomus macrocheilu	<u> </u>	S
Longnose sucker	Catostomus catostomus	С	S

Five white sturgeon were relocated from below Libby Dam to the reservoir. At least one of these fish moved upriver out of the reservoir and two were reported caught by anglers.

RESERVOIR HABITAT

Methods

Libby Reservoir has been divided into three areas for study purposes by the Montana Department of Fish, Wildlife and Parks (Huston et al. 1984, Chisholm and Fraley 1986). Segregation into three geographic areas was based on reservoir morphometry, effects of reservoir drawdown, and political boundaries (Figure 2).

The 'nearshore' or littoral zone was defined as that portion of the reservoir within 100 m of the shoreline. The remaining area of the reservoir was designated as the limnetic zone.

Contour maps of the area impounded by Libby Dam [(USACOE, File Number E53-1-154, Sheets 1-37, 1972 and British Columbia Ministry of the Environment, Drawings M-249-C, Sheets 1-63, 1969)] were digitized to allow for computer access and storage. Each ten foot contour interval wasentered for all reservoir maps from full pool elevation (2,459 ft above mean sea level) to 2,190 ft, and 30 foot contours wereentered from 2,190 ft to the reservoir bottom. Water surface area and volume were calculated using equations generated from this data which mathematically defined a cubic spline relationship between elevation and the variables.

Results and Discussion

Reservoir operation differentially affects the three study areas of the reservoir -- a function of their basic morphology and proximity to the dam (Figure 3). Annual vertical fluctuations of up to 52.4 m (172 ft) occur, reducing total volume nearly 85 percent and mean depth by 51 percent. Drawdown to the minimum operational pool reduces the length of reservoir by 53 percent (to 67.6 km), the volume by 85 percent (to 1.08 km 3), and the surface area by 69 percent (to 58.6 km²). Relative changes in water volume and surface area are greatest in the Canada and Rexford areas and least in the Tenmile area. At full pool, the Canada area comprises 38 percent of the total surface area, and a 100 - ft drawdown reduces the Canada area to less than 12 percent of the total (Appendix A, Table Al). Conversely, the relative percent of total surface area in the Rexford and Tenmile areas increase from comprising 24.7 and 37.2 percent of the total at full pool to 31.9 and 56.5 percent at a 100-ft drawdown, respectively (Appendix A, Table Al). A graph of the relationship of reservoir elevation to surface area and volume is provided in Appendix A, Figures Al and A2. The mean depth of 38.1 m at full pool is reduces to 8.6 m at 172-ft drawdown.

Reservoir drawdown has averaged 118 ft since 1974 (Table 3). Full pool (2,459 ft above msl) was first reached in July 1974 and the reservoir has attained that elevation 10 of the 14 years since. Deepest drafts occurred in 1974 (153 ft), 1975 (172 ft), and 1976 (152 ft), and in two oftheseyears (1974 and 1976) the

reservoir was refilled. The average time spent at full pool was over one month (41.6 d); this figure does not include those years where full pool was not reached. The mean elevation reached for a non-refill year (post 1974) was 2,442 ft above msl or 17 ft below full pool.

During the five years of this research project, the reservoir inflow equaled annual outflow volume from Libby Dam, except in 1985 when the reservoir did not refill. Maximum inflow occurred during May for all years from 1983 through 1987, whereas, in general maximum outflow occurred during November (Appendix A, Figures A3, A4). This annual pattern of inflow and outflow produced large fluctuations in reservoir surface elevation (Appendix A, Figure A5). Graphs of mean monthly outflow temperature and dam withdrawal elevation for 1983 through 1987 are also provided in Appendix A (Figures A6, A7). Withdrawal elevation was generally 60 to 70 ft below the surface elevation of the reservoir from May through November.

Management of fall outflows at Libby Reservoir has changed since 1984. By comparing year-end reservoir surface elevations before and after 1984, it is apparent that the reservoir is being drafted to a greater depth at an earlier time. Mean reservoir elevation for December 31 from 1973 to 1983 was 2,400.6 ft (standard deviation = 15.2) versus 2,389.8 ft (standard deviation=2.2) for the years 1984 to 1987. A one-tailedt-test confirmed that the later year elevations were statistically less than those prior to 1984 (t=1.78, df=8.73, p=0.034). Within the operational limits of the reservoir (2,287 ft above msl), the additional 10-ft drawdown by December 31 represents a 13 percent reduction in available volume. Deeper draft before January is likely to lead to reduced flexibility in drawdown management, as these drafts are taking place before the first snowpack forecasts are issued on January 1 of each year. The resulting power is currently marketed as surplus firmpower, which does not supplant thefirmpowercommittments.

Lake-fill and hydraulic residence are expressions of the time it takes to refill a reservoir at a given inflow and how long thewaterstays in the reservoir at a given outflow, respectively. Lake-fill (or retention) times are expressed mathematically as volume (V) divided by inflow (I) and the expression for hydraulic residence is volume/outflow (V/O) (Woods and Falter 1982).

Straskraba (1973) considered lake-fill (retention) time to be a major key to understanding reservoir limnology. Retention time affects thermal structure (Straskraba 1973), water currents and nutrients, and therefore the degree of eutrophy (Dillon 1975) and primary production in a reservoir (Dickman 1969, Woods 1979, St. John et al. 1976).

Lake-fill times are greatest in Libby Reservoir in the late summer months (when inflow is smallest and volume is the largest) and minimum during runoff months (when inflow is large and reservoir volume is relatively small following fallandwinter drawdown). Hydraulic residence times in Libby Reservoir are greatest during the winter/spring refill or the summer months (when 0 is small or V is approaching capacity, respectively). Minimum hydraulic residence times normally occur during the fall and winter months, when dam outflow is at its maximum and the volume has been reduced from drafting.

WATER QUALITY

Methods

A permanent sampling buoy was placed within each area (an established United States Geological Survey [USGS] buoy was used in the Termile area) where water quality and zooplankton sampling were conducted. In addition, eight to twelve transects were established between recognizable landmarks in each area. These transects were further subdivided into east, west, and mid reservoir stations for random sampling.

Vertical layers of the water column were defined using measurements of light penetration, water temperature, dissolved oxygen, pH, and conductivity (umhos/cm). A Protomatic photometer and a Martek Mark V digital water quality analyzer were used to measure the above variables. Sampling was conducted in each geographic area on a biweekly basis from May through October, and monthly from November through April unless dewatering of boat ramps or ice formation prohibited access (Table 4).

Martek sampling was done using methods followed by the USGS (Greeson et al. 1977). Water quality measurements were taken at the surface, at one meter, at every two meters to 15 m, at every three meters to 60 m, and at every five meters to 95 m or the bottom. Laboratory calibration of the Martek was done prior to field sampling following the manufacturer's instructions. Water samples were also taken with a VanDorn sampler at the surface, 11 m, and 21 m. A modified Winkler titration (APHA 1975) was used to determine the dissolved oxygen (D.O.) content of these samples. These D.O. values verified proper calibration of the Martek meter. Incident light was recorded above the water's surface and at one meter intervals to a depth of 30 m or until light intensity was one percent or less of the incident light (defined as the lower boundary of the euphotic zone [Talling 1962]). Secchi disk readings were taken following the considerations presented by Wetzel (1975).

Isopleths of temperature, pH, dissolved oxygen, and conductivity were plotted for each sample station through time using the USGS program STAMPEDE.

Results and Discussion

Oxygen and pH were not found to be limiting at any time in Libby Reservoir, generally meeting all salmonid requirements as reported in Piper et al. (1982). Dissolved oxygen ranged between 7 and 15 ppm in 1987 (Appendix B, Figures Bl through B3), and pH ranged from 6.8 to 8.9 (Appendix B, Figures B4 through B6). Generally those species that live in cold or cool waters of low primary productivity do best at pH 6.5 to 9 (Piper et al. 1982).

Water temperatures ranged from 1°C to 21°C in 1986, and from 1°C to 25°C in 1987. Maximum surface temperatures occurred in

Table 4. Limnological sampling frequency on Libby Reservoir from 1983 through 1987.

late July and August of both years. Optimum temperature range for growth of kokanee salmon, currently the most sought-after fish in the reservoir, is listed as 10-15°C by Piper et al. (1982). Optimum growth conditions in terms of temperature occur from May through November for the Tenmile and Rexford areas and May through October for the Canada area (Appendix B, Figures B7 through B9). The greatest volume of water with these temperatures is generally present from May through July.

Libby Reservoir did not thermally stratify to any degree during 1986 or 1987, as evidenced by the wide spacing of isotherms on the Tenmile, Rexford, and Canada graphs (Appendix B, Figures B7 through B9). The weak thermal structure of Libby Reservoir was largely attributed to reservoir operation. Water movements in reservoirs result from the interactions of reservoir operations, basin morphology and climate, thermal stratification, and currents (Woods and Falter 1982). In many reservoirs, the unsteady nature of inflow and outflow currents (i.e. reservoir operation) is largely responsible for continual water movement, and is strongly related to water quality parameters such as temperature and oxygen (Wunderlich 1971).

Euphotic zone depth averaged 10 m in 1986 and 8 m in 1987 (Table 5). lowest levels of light penetration occurred during spring runoff; euphotic zone depth averaged 5 m in June of 1986 and 4 m in May of 1987. These low levels are due to turbidity caused by large loads of suspended sediments carried into the reservoir by the Kootenai River during spring runoff (Bonde and Bush 1975); the effect is compounds by the low water volumes in the spring resulting from the winter draft of the reservoir. Deepest euphotic zone depths occur during the winter months in the Tenmile area and during late winter and summer months in the Rexford and Canada areas, respectively (Appendix B, Figures B10 through B12).

Table 5. Mean euphotic zone depth (m) (top line) and secchi disk depth (m) (bottom line) measured in Libby Reservoir, July 1983 through December 1987. Sample size is in parenthesis.

PRIMARY PRODUCTION

Methods

Primary production measurements were made at three-week intervals from May to November, 1986, and then at four-week intervals until April, 1987. Four stations within the reservoir were monitored: Tenmile, Stonehill near Peck Gulch, International Border, and Canada near Kikomun Provincial Park. productivity was measured using the light/dark bottle technique and ¹⁴C radioisotope tracer (Wetzel and Likens 1979). This method is particularily applicable to slow moving or standing, low productivity waters such as Libby Reservoir (Janzer et al. 1973). For each station, water samples were collected at discrete depths (surface, 1, 3, 5, 10, 15, 20, and 25 m) and subsamples drawn off into one clear and one opaque bottle. These were inoculated with $^{14}\mathrm{C}$ and then suspended at the collection depth and incubated for three to seven hours near midday. The algae from each bottle was then separated by filtration for analysis of 14C uptake through liquid scintillation counting. Total daily solar radiation was measured by a pyronometer set and monitored at the Murray Springs Fish Hatchery.

Rates were estimated using the following general equation and

where '12C available' was estimated from alkalinity measurements, '14C available I was calculated from the specific activity of the NaH¹⁴CO₃ stock solution and '14C uptake' was measured by liquid scintillation counting of the filtered algae.

Daily volumetric production rates $(mgC/m^3/d)$ at each station were calculated from the rates measured during the incubation period by normalization to total daily light (total langleys/langleys during the incubation period). Volumetric rates for each depth sampled were then integrated to give a water-column or areal productivity rate $(mgC/m^2/d)$.

Results and Discussion

Highest daily areal productivity rates were measured at the Termile and Border stations but rates were highly variable between sampling areas (Table 6). Direct statistical comparisons of differences among stations were not performed because photosynthetic activity is not constant throughout the light day or euphotic zone, nor is it symmetrical with regard to midday (Vollenweider 1965). Therefore, differences in the period of the light day sampled preclude statistical tests between areas.

Table 6. Primary productivity data collected from Libby Reservoir, May 1986 through January 1987. The rates are expressed as daily areal rates $(mgC/m^2/d)$.

Daily areal productivity rates were highest during July, with measured productivity in 1986 ranging between 63.9 and 588.0 mg $\rm C/m^2/d$ (Table 7). This is similar to the production rates measured from 1972 to 1980 reported by Woods (1982) as ranging from 0.4 to 420 mg $\rm C/m^2/d$.

Monthly averages of observed secchi disk depth, surface water temperature and month of the year explained 94 percent of the variation in 1986 phytoplankton productivity rates (R = 0.941; $F_{3,3}$ =15.94; P=0.0239). Similarly, monthly averages of the euphotic zone depth, surface water temperature and month of the year also explained 94 percent of the variance in measured productivity rates (R^2 =0.939; F_3 ₃=15.56; P=0.0247). Within any given area, the lowest daily areal primary production rates were observed in December (Table 7). These results imply that the overriding factors determining productivity in Libby Reservoir at this time are light and temperature. Woods (1982) presented the results of multiple regression analysis in which six variables were used to predict daily arealprimary productivity in Libby Reservoir from data gathered during 1972 to 1975. The relationship developed explained 50 percent of the variance. Disparity with our results may reflect the different techniques used, especially with regard to integration of incident light during incubation of samples, or may indicate a real change in the importance of factors limiting photosynthetic activity on Libby Reservoir.

Woods (1979) concluded that the quantity of light received by phytoplankton was the dominant influence on primary productivity in the reservoir: however no one single environmental variable fully accounted for the seasonal variations in primary productivity. He identified three processes as having an effect on the light availabletophytoplankton. First, a weakthermal structure in the reservoir allowed phytoplankton to be circulated out of the euphotic zone. The operational schedule of the reservoir, in conjunction with large seasonal inflows, produced the weakthermal structure. Second, thelargelyturbidinflows during spring runoff substantially reduced euphotic zone depths. Third, the amount of light available was largely dependent on seasonal and meteorological variations in incident solar radiation.

The extent to which nutrients determine phytoplankon production in Libby Reservoir is not fully known. Woods and Falter (1982) reported that nitrogen and phosphorous data taken concurrently with areal productivity did not appear to account for the seasonal variations in productivity. During 1972 to 1980, the reservoir was classifiable as eutrophic, based on Vollenweider's (1975) nutrient loading model (Woods 1982). However, the average daily areal primary productivity during 1972 to 1980 characterized its trophic state as oligotrophic. This discrepancy is attributed to the failure of the nutrient loading model to adequately account for limnological processes within the resevoir which affected the availability of influent nutrient loadings to phytoplankton (Woods 1982).

Table 7. Mean monthly values of variables used in regression analysis of daily areal primary productivity measured in Libby Reservoir, 1986.

Month	Productivity rate (mgC/m ² /d)	Surface temp (^O C)	Euphotic zone (m)	Secchi depth (m)

NOV			10	2.8		
Dec	79.20	4.7	8	3.3		

Our technique assumes that all primary productivity is from phytoplankton and that periphyton primary productivity was minimal, which can generally be assumed in large, deep lakes (Likens 1975). Calculations assume that photosynthetic activity is constant through the day, which it is not, but does vary least between the second and fourth light periods (Vollenweider 1965), whaen our sampling was conducted. Also, the method used to measure productivity quantified particulate organic carbon, not dissolved organic carbon, which may be important at low phytoplankton growth rates (Harris 1986). Another potential bias inherent with the ¹⁴C light and dark bottle method is that the in situ incubations create an artificial environment by isolating phytoplankton from turbulence and circulation through light gradients. Woods and Falter (1982) believed this bias was existent on Libby Reservoir, but minimal.

SECONDARY PRODUCTION

DATA ANALYSIS

Data sets were analyzed using Statistical Package for Social Sciences (SPSS, Nie et al. 1979) and Statgraphics (Statistical Graphics corporation 1987) plotting routines. Parametric analysis techniques were used whenever possible because these methods are useful in summarizing the underlying structure of a body of data (Andrews et al. 1971). Transformations to normalize data were derived following the techniques presented by Taylor (1965). Statistical significance for all tests was chosen as p < 0.05.

BENTHOS

Methods

Three replicate dredge samples were collected from three elevational strata in each area. The three elevational strata were classified as: frequently dewatered or shallow (between full pool and the 2,369-foot contour), occasionally dewatered or mid (between 2,368- and 2,287-foot contours), and permanently wetted or deep (below the 2,287 foot contour). Samples were not collected in substrates exposed by drawdown.

Sampling was performed using a Peterson benthic dredge equipped with two auxillary weights and ventilation holes in the top to minimize shock waves. The dredge has an empty weight of 93 pounds and a sampling area of one square foot. A hydraulic winch spooled with 1/4-inch aircraft cable lowered the dredge to sample depths determined by sonar. Samples were transferred to sealable buckets and brought back to the lab for analysis.

Benthic samples were wet-sieved using 5.6-, 0.85- and 0.52-mm sieves. The material retained in the 0.52-mm sieve were brought to the laboratory where all macroinvertebrates were picked from the sample and identified to order or class (Diptera and Oligocheatea). Samples were preserved in a formalin preservative prior to fall 1986 and in a 95 percent ethanol solution after fall 1986. The number of each order or class was recorded. Densities were expressed as number per square meter of reservoir bed by elevational strata and geographic area.

As stated above, all ANOVA tests were performed by averaging the three replicates for each sample aone and date and using a log transformation to normalize the data.

Results and Discussion

A total of 635 benthic samples were collected between 1983 and 1987. forty-four percent of the samples were taken in the Termile area, 42 percent in the Rexford area, and 14 percent were collected in the Canada area. Sampling effort was evenly distributed among the drawdown zones; the shallow zone comprised

32.4 percent of the samples, the mid zone comprised 34.2 percent, and the deep zone made up the remaining 33.4 percent.

Existing reservoir surface elevations on sampling dates ranged between 2,350 ft msl and full pool (2,459 ftmsl). Samples were collected from depths of 0.9 (3 ft) to 82 m (270 ft).

From 1983 to 1987, benthic invertebrate densities in the shallow, mid and deep zones of Libby Reservoir averaged 178.7, 569.9, and 1,099.8 organisms/m², respectively (Table 8). The densities of dipterans in Libby Reservoir were slightly higher than in nearby Hungry Horse Reservoir (May 1988), which averaged 337 dipterans/m². When compared to North American reservoirs in general, densities of dipterans in Libby Reservoir are low. For example, Cowell and Hudson (1968) recorded 60,620 Chironomids/m² in Lake Francis Case Reservoir in the Missouri River system.

Studies by Grimas (1961) on a Swedish lake, and Peterka (1972) on a non-fluctuating reservoir in North Dakota, show that benthos densities generally decline from the littoral to the profundal zone. The reverse pattern of abundance existed in Libby Reservoir during spring and fall (1984-1987), as density of dipterans declined from the profundal to the littoral zone (Figure 4). Our results are consistent with the findings of Kaster and Jacobi (1978) in Big Eau Pleine Reservoir which also experiences water level fluctuations.

The exact nature of drawdown effects on benthos in Libby Reservoir is unclear. Grimas (1961) and Fillion (1967) found the greatest abundance of benthos immediately below the drawdown limit. Between 1983 and 1987, the drawdown limit in Libby Reservoir varied by 8.5 m. In one year, 1983, the mid zone was not even partially dewatered. The deep zone of Libby Reservoir, in which there was no dewatering during the study period, probably serves as a refuge for dipteran larvae during the period of drawdown. Unexplained is why our data do not support a similar role for the mid zone. In all years studied, the deep zone had higher densities of dipterans in spring (March, April, May, June) than the other two zones (Figure 5). During summer (July, August, September) the mid zone had greater densities than the deep zone (Figure 6). The reduced density in the deep zone from spring to summer is probably the result of losses during the peak spring emergence from the deep zone and dispersal of larvae from the deep zone to the expanding mid and shallow zones as the reservoir Many dipteran larvae, especially early instars, fills. demonstrate positive phototropism which allows efficient colonization of advancing water margins (McLacklan 1969, Oliver 1971).

The shallow and mid zones showed continuous increases from spring through fall suggesting that those zones were being colonized from the deep zone at a rate exceeding losses from emergence. Since the seasonal abundance patterns in the shallow and mid zones were so similar, they both seem to be strongly influenced by colonization. Therefore, dipterans in Libby

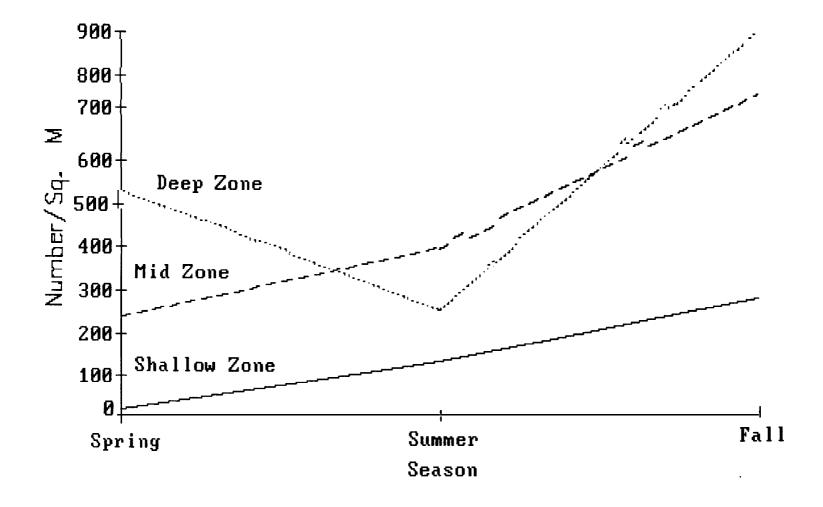

Figure 4. Average number of dipterans per square meter in spring (March through June), summer (July through September), and fall (October through December) in three depth zones in the Tenmile and Rexford areas of Libby Reservoir, 1984 through 1987.

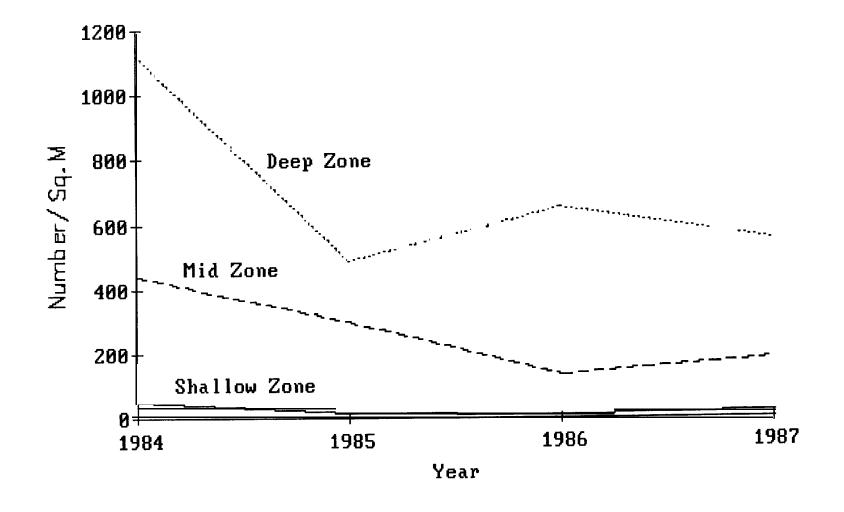

Figure 5. Average number of dimterans per square meter during soring (March through June) in three depth zones in the Tenmile and Rexford areas of Libby Reservoir, 1984 through 1987.

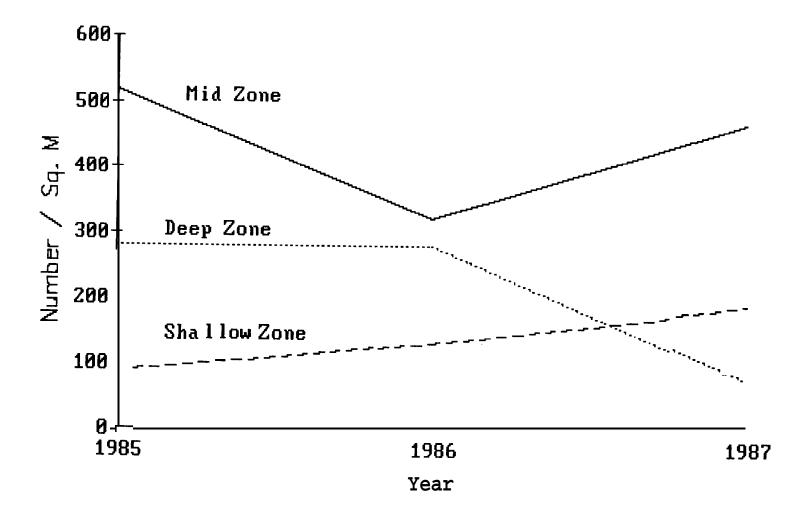

Figure 6. Average number of dipterans per square meter during summer (July through September), in three depth zones in the Tenmile and Rexford areas of Libby Reservoir, 1985 through 1987.

Reservoir do not seem to concentrate near the drawdown limit as dipterans in the reservoirs studied by Grimas (1961) and Fillion (1967). Identification of chironomid larvae to genus and species groups as planned for 1989 may further elucidate the effects of drawdown by zone.

Diptera constituted the predominant group in the benthic fauna of each drawdown zone in Libby Reservoir. The shallow zone contained the highest percentage of Diptera, comprising an average of 84.17 percent of the total density for that zone, followed by the mid drawdown zone which averaged 73.99 percent, and the deep zone which averaged 53.81 percent. Total number of Diptera encountered in the samples ranged from zero to 278 organisms with an overall mean of 34.2 per sample. Total number of Oligochaeta in our samples ranged from zero to 941 organisms, buttheoverall mean was 23.1 per sample. An overall average of 69.9 percent of all benthic invertebrates sampled were Diptera.

Overall benthic densitie svaried among the study areas of the reservoir, and were related to the drawdown zone and the class of organism. In the frequently dewatered or shallow zone, density of Oligochaeta for 1983 through 1987 was statistically different ($F_{2\ 30}=16.51$, p<0.0001). Multiple comparisons (SNK) indicated that Canada bad a statistically higher mean density of Oligochaeta than the other areas of the reservoir. These conditions did not exist between the Rexford and Tenmile areas.

Maintenance of the higher densities of Oligochaeta in dewatered drawdown zones can occur by the organism remaining in the substrate or by rapid recolonization of Oligochaeta in early summer when the zone is inundated. Recolonization is dependent on the nature of the substrate (Kaster and Jacobi 1978), and possible substrate differences (particle size, slope, proximity to water) between Canada (which remains the most riverine) and the other two areas may account for thevarying abundance of Oligochaeta. In Big Eau Pleine Reservoir, Wisconsin, benthos recolonized more rapidly and were of greater density in substrates containing large amounts of detritus or organic matter than in sandy substrates (Kaster and Jacobi 1978).

Greater nutrient levels in the Canada area relative to the Tenmile and Rexford areas may also explain the increased abundance of Oligochaetes in Canada. Dominance of oligochaetes in the macrobenthos is typical of eutrophic waters (Beeton 1961, Thut 1969). Oligochaetes generally increase in dominance in the benthos during the processs of eutrophication (Wetzel 1975).

In the occasionally dewatered or mid zone of the reservoir, benthic densities varied between the Tenmile and Rexford areas. (The Canada area was not deep enough to have a mid zone-- 91- to 172-foot drawdown.) Overall benthic invertebrate density was significantly greater in the Tenmile area ($F_{1.67}$ =5.327, p=0.024). Greater numbers of Diptera accounted for the statistical significance ($F_{1.66}$ =7.905, p=0.0065); mean density of Diptera

(replicates averaged) in the Tenmile area was $386.6/m^2$ versus $188.1/m^2$ in the Rexford area.

The permanently wetted or deep zone in the Rexford area contained a higher density of Diptera and Oligochaeta than the other two areas. Mean density (replicates averaged) of Diptera in the Rexford area for 1983 through 1987 was 482.3 per square meter. This value is significantly greater than those found in the Canada area, but not in Termile.

In the permanently wetted zone, Student-Neuman-Keuls multiple range test indicated that Oligochaeta densities were significantly greater in the Rexford area than in the Tenmile and Canada areas. ($F_{2.74}$ =14.434, p<0.0001).

SURFACE MACROINVERIEBRATES

Methods

Macroinvertebrates on the surface of the reservoir were sampled using a tapered net constructed of 3.17-mm mesh near the mouth and 1.59-mm mesh in the midsection that tapered to a 100-mm diameter collar. The mouth of the net was rectangular 1.0 m wide by 0.3 m high. A removable plastic bucket with a panel of 80-micronnitex netting was attached to the collar at the end of the net. The net was towed so that it sampled a 1-m swath of the reservoir's surface.

Three sites were sampled biweekly or monthly. Sample sites were selected randomly using established transects as starting points. Each sample site consisted of two sampling runs, one nearshore (less than 100 m from shore) and one limnetic (greater than 100 m from shore). Nearshore tows were made in a zig-zag pattern along shore while limnetic tows were made in a direction angling away from shore.

Initially, surface tows were made by towing the net for ten minutes at a constant speed of 1.0 m/sec. After July, 1985, this method was simplified by the use of a digital knotlog (Signet, Model MK 267). This instrument accurately measured the sampling distance of 600 m.

All macroinvertebrates were removed from the bucket and net after each tow and placed in a labeled vial containing a formalin preservative (prior to fall 1986) or in a 95 percent ethanol solution (after fall 1986. Macroinvertebrates in each sample were identified to order and counted in the laboratory. Blotted wet weights were measured in grams. Densities and biomasses of surface macroinvertebrates were expressed as number per hectare and grams per hectare, respectively.

Results and Discussion

Surface insect tows were performed between 1983 and 1987. There appeared to be very little consistency in insect densities among years or distance from shore, and variances were very high (Table 9). A maximum density of over 1,950 terrestrial invertebrates per hectare was attained in the nearshore zone of the Termile area in 1985, a more than 140-fold increase over the minimum value recorded in the nearshore zone of the Rexford area in 1983.

The yearly trend of surface invertebrate densities was upward through 1985. A sharp decrease was experienced in1986 and then densities increased again in 1987. This was true for the Tenmile and Rexford areas; conversely, the densities in Canada were relatively high in 1983 and tended to decrease except in 1986 when numbers increased. Water levels were similar in 1986 to other years so there is no obvious explanation for the difference.

Aquatic insect densities were generally lower than those of terrestrial invertebrates but followed the same trends. Densities ranged from a low of 6.4/ha in 1983 in the nearshore zone of the Rexford area to a high of greater than 200/ha in the nearshore zone of the Canada area in 1987. The lower number of dipterans caught does not parallel the numbers that were seen on emergence traps. This difference may be due to difficulty of capture. The small size of some dipterans (Merrit and Cummins 1984; Oliver 1971) and their habit of generally emerging in darkness and flying immediately upon emergence (Mundie 1959) may allow the dipterans to escape through the mesh or avoid capture.

Yearly trends in density for aquatic invertebrates were similar to those of the terrestrials. The densities of aquatic invertebrates in the Tenmile and Rexford areas mirrored the terrestrials during the study period, showing increases through 1985 followed by a large decrease in 1986 and an increase through 1987. The density of terrestrial and aquatic invertebrates decreased in the Canada area from 1983 to 1984, but increased from 1985 to 1987.

The densities of macroinvertebrates captured in the nearshore zone were not consistent with those in the limnetic zone. Although the highest number of terrestrials were generally captured near shore, variances were so high that the difference was not statistically significant ($F_{1\ 780} = 0.2290$, p = .6324), and in several instances, higher densities were found in the limnetic zone (Table 9). Wind, water currents, and wave action are the likely reasons for the density differences between the two zones.

A pattern appeared when densities of invertebrates were compared among areas. It was found that terrestrial numbers were generally lower and aquatic numbers were generally higher in the Rexford area than in the Tenmile area. This was true on both a

yearly and monthly basis (Table 9 and Appendix C, Tables Cl - C18).

A possible reason for the Tenmile area containing higher numbers of terrestrial invertebrates involves the morphology of the reservoir. The banks of the Tenmile area are generally narrow and steep. In contrast, much of the Rexford area is wider and shallower than the Tenmile area, and contains large areas of bays and shallow water. Therefore, when reservoir levels are lowered, large expanses of barren ground are exposed, increasing the distance from water to shoreline vegetation. Norlin (1967) suggested that barren ground facilitates rising thermal air currents that impede trasport of airborn insects over a body of water The effect in the Tenmile area wouldnotbe as pronounced since there is less barren ground and the vegetation is closer to the water.

The reason for greater aquatic invert&rate densities in the Rexford area is likely two-fold. First, the substrate composition in the Rexford area may be more conducive to dipteran production, which is consistent with results of the benthic sampling. Densities of dipteran larvae are greater in the permanently wetted zone of the Rexford area than in any Tenmile zone. Secondly, at full pool and during drawdown there remains large areas of relatively shallow water in the Rexford area. This leads to a greater amount of bottom that is euphotic, and hence more productive. Welch et al. (1988) found that dipteran emergence increased with increased primary production. Reservoir morphology in the Tenmile area lacks the positive components for dipteran productionthatarepresent in the Rexford area.

All areas were similar with respect to types of invertebrates caught and monthly patterns of capture. The density of individual invertebrate types, in decreasing order, were Hymenoptera, aquatic Diptera, Homoptera, Coleoptera, Hemiptera, and Arachnida.

When viewed monthly, major peaks in densities did not coincide for terrestrials and aquatics. In general, terrestrials remained at relatively low densities through July and then peaked abruptly in August. After August, numbers decreased again but remained at higher levels than months previous to July (Figure 7). Aquatic invertebrate densities peaked in April and May and then to a lesser extent again in August (Figure 8).

Individual invertebrate types varied among months. Aquatic dipterans peaked earliest. They comprised approximately 55 and 65 percent of the total invertebrate drift in April and May, respectively. Surface deposition of Coleoptera was greatest in early summer, peaking in June and comprising about 31 percent of the total input. Input of Hymenoptera (primarily ants) was greatest in August when they comprised almost 45 percent of the total input of surface film invertebrates. Hemiptera and to a lesser extent Arachnida were important from September through November. Homoptera (mostly leafhoppers) were consistently

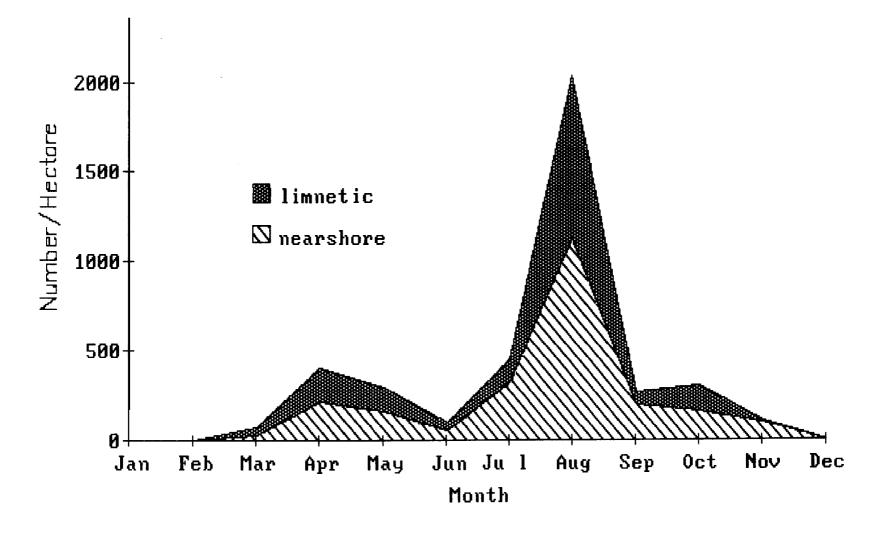

Figure 7.. Estimated densities of terrestrial macroinvertebrates found on the surface of Libby Reservoir, 1983 through 1987.

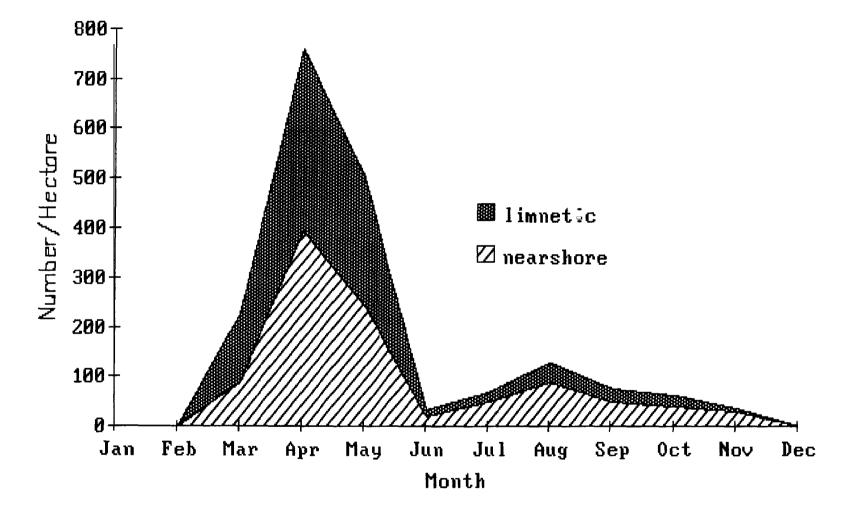

Figure 8. Estimated densities of aquatic macroinvertebrates found on the surface of Libby Reservoir, 1983 through 1987.

important from July through November, comprising about 30 percent of the total input of invertebrates for those months.

Biomass of surface invertebrates followed the same trends as those shown for density (Table 10 and Appendix C, Tables C19 - C36). Tenmile tended to have the greatest terrestrial biomass while Rexford had the greatest aquatic biomass. Terrestrial biomass was greater than 61 percent of total biomass for all months except April and May (56 percent and 43 percent, respectively) and was as high as 98 percent. Two peaks in biomass occurred (Appendix C, Tables C19 - C36). One occurred in April and May and was fueled by the large Coleoptera that were captured. The second peak was seen in August and contained the Hymenoptera that was discussed earlier.

AQUATIC INSECT EMERGENCE

Methods

Insect emergence was determined at the Tenmile area of Libby Reservoir. Four replicate samples were collected weekly when possible for each of the three determined elevational strata (frequently dewatered or shallow, occasionally dewatered or mid, and permanently wetted or deep).

Sampling was accomplished using a 1-m square emergence trap (Figure 9) constructed of 1/16-inch acrylic (May et al. 1988). Floatation of the trap was accomplished with styrofoam strips that were fastened to the bottom of the trap. Four traps were permanently anchored at each strata and rope was added or removed topreventthem from sinking or floating intoanadjacentstratum as water levels raised or dropped.

Vents were cut into the sides of the trap and the catch basin to reduce condensation that might impede movement of an emerging insect. The holes were covered with 120-um cloth to prevent escape of the insects. Automotive antifreeze was used as a preservative for the traps in the field to preven dessication during the hot months and freezing during the cold months. Each week all traps were checked and their contents removed. Samples were then placed in a formalin preservative (prior to fall 1986) or in a 95 percent ethanol solution (after fall 1986) and transferred to the lab for analysis.

Samples were separated by order (Diptera, other) in the lab and their numbers and dry weights recorded for each of the strata. Densities were expressed as number per square meter and weights as grams per square meter of reservoir by elevational area.

Results and Discussion

Dipteran emergence was sampled between June and December, 1986, and between April and October, 1987. Emerging insects were almost exclusively dipterans; other types of invertebrates were identified in only two of the 376 samples. Energence of dipterans differed by year, by drawdown zone, and by season.

In both years, the shallow and mid zones had considerably higher densities and total numbers of emerging insects than did the deep zone (Table 11). In 1986, the highest density was found in the shallow zone $(18/m^2/wk)$, followed by the mid zone $(11/m^2/wk)$ and the deep zone $(3/m^2/wk)$. In 1987, the mid zone had the highest density followed by the shallow zone and the deep zone (68, 52 and 34/m /wk, respectively). Statistical comparison of total yearly densities or numbers between1986 and 1987 was not attempted because of the differences in sampling times.

The monthly trends in emergence were fairly similar between years (Table 12). In 1986, peak emergence was in June in the shallow and mid zones with the mid zone having the greatest

density of emergers $(108/m^2/wk)$. After June, emergence decreased and remained low in the mid zone. In the shallow zone, emergence increased significantly $(f_{4.72}=26.002, p<.001)$ in August and September over the July levels; this trend is also supportedby surface invertebrate tow data. Densities then decreased to little or nothing for the rest of the year, with no emergers captured in November or December. Sampling in the deep zone did notbegin until August, and densities were consistently low $(0-4/m^2/wk)$. In 1987, shallow zone densities peaked in May $(112/m^2/wk)$, dropped in June and July, and then increased again in August. Mid zone densities peaked in June $(143/m^2/wk)$ and decreased through the rest of the year. Rates of emergence in the deep zone was less than in the other two zones, although it had high rates of emergence in May and June $(87 \text{ and } 61/m^2/wk)$, respectively).

Warmer water temperatures in the shallow zone relative to the other zones may account for the high rates of emergence there. Oliver (1971) stated that larvae mature faster in warmer water. In Libby Reservoir, this means there is potential for a continued supply of dipterans throughout the warmer months when water is available. But it is also probable that the fullpotential of the shallow zone will never be realized due to water level fluctuations which result in a reduction in wetted substrate during the peak emergence times.

The high rates of emergence in May 1987 in the shallow zone were not expected, because of the short interval between the time this zone was wetted and the high rates of emergence. Possible explanations for this include: bi- or multi-voltine species with short life cycles that laid eggs in this zone as soon as it became wetted: eggs or larvae that overwintered in the shallow zone that hatched or matured immediately upon wetting (The phenomenon of over-wintering has been documented by Danell 1981, Merritt and Cummins 1984, Paterson and Fernando 1969); wind, wave or current action forceing emerging pupae into the shoreline or emerging pupae actively seeking warmer water in which to emerge, To more fully understand the true mechanisms affecting the shallow zone emergence patterns, species or genus identification is essential so that life histories and mergence patterns can be ascertained.

The trends of densities with respect to the depth zones do not necessarily follow the trends suggested by benthic sampling. As was stated in the benthos section, the deep zone had the highest number of dipterans and the mid zone was second. The trends are reversed for captures in the energence traps. There are several possible explanations for this. First, sampling may have been biased by wind and wave action around the traps and currents under the surface, resulting in insects of one zone emerging from the surface in another zone and biasing sample numbers. Second, the large number of benthic dipterans in the deep zone may be serving as a pool for the mid and shallow zone, and are recolonizing the shallower depths (as either eggs or larvae) as water temperatures warm. Third, the shallow zone may supoprt more multi-voltine species, resulting in relatively greater emergence as compared to the deeper zones.

ZOOPLANKTON

Methods

Three 30-m (or the entire water column whendepth was less than 30 m) vertical plankton tows were made biweekly from April through October and monthly from November through April in each geographic area of the reservoir. A 0.3-m diameter Wisconsin plankton net was used for all tows. One tow was made at the permanent sampling buoy and two tows were made at randomly selected points on established transects in each area.

A plankton trap similar to that described by Schindler (1969) was used monthly to sample the vertical plankton distribution at permanent sample buoys in each geographic area. The trap sampled a 28.1-liter volume of water and each sampling series consisted of nine discrete samples collected at the surface, 3, 6, 9, 12, 15, 20, 25 and 30 m.

All zooplankton samples were preserved in a solution of water, methyl alcohol, formalin and acetic acid from September 1983 through November 1986 and in 95 percent ethyl alcohol from December 1986 to the present. A comparison of zooplankton lengths was performed on 20 subsamples from the December 1986 series, half preserved in formalin and half preserved with alcohol, to document the effect of this preservative change.

Vertical tow samples were diluted in the laboratory to a density of about 20-25 organisms/ml. Zooplankton were enumerated and identified to genus in each of five subsamples (5 ml) taken from the solution. Subsamples were averaged to estimate densities (number per liter) of zooplankton. Schindler trap samples were counted in entirety, and all zooplankton were identified to genus. For both methods, carapace lengths of individual planktors were measured; for vertical tows, all individuals were measured from one randomly chosen subsample; for Schindler samples, up to 20 individuals were measured from each sample. Carapace length data were segregated into 0.5-mm length groups for each genus and each group was averaged Biomass of zooplankton was estimated using the length-weight relationship described by Shepard (1985).

To determine if statistical differences in zooplankton abundances existed between thereservoir study areas or within the years of the study, the Kruskal-Wallis nonparametric analysis of variance test and nonparametric Tukey-type multiple comparisons were applied (Zar 1984). Comparisons were performed after the Kruskal-Wallis test revealed differences existed at the 0.05 level of significance. Replicates collected on each sample date were averaged within each study area for the statistical analysis.

Results and Discussion

Horizontal Distribution

From September 1983 through September 1987, 434 vertical plankton tows were collected from Libby Reservoir. Surface temperatures ranged between 6 and 24.8°C during the sampling period. Sampling occurred when reservoir elevations ranged between 2,342 ft above msl (117-foot drawdown) and full pool (2,459 ft).

Irving (1987) identified eleven species of macro-zooplankton in Libby Reservoir during 1977 and 1978 (Table 13) and it is likely that these are the species currently present in Libby Reservoir. The most abundant species he encountered were <u>Daphnia</u> schodleri, Diaptomus tyrrelli, and Cyclops bicuspidatus thomasi.

There were four main genera of zooplankton identified in Libby Reservoir during this study: <a href="Mossing.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/Bosming.com/B

The copepods, <u>Diaptomus</u> and <u>Cyclops</u>, comprised the greatest portion of zooplankton sampled in the reservoir: combined they acounted for 67.5 to 77.7 percentofthe zooplankton population from 1983 through 1987 (Table 14). Cladoceran densities, particularly <u>Bosmina</u>, varied greatly during the five years of sampling. In 1984 and 1985, <u>Bosmina</u> comprised 9.3 percent and 6.7 percent of the zooplankton population, respectively, while in 1983 and 1986, <u>Bosmina</u> accounted for 1.1 percent and 0.4 percent, respectively.

The apparent changes in the zooplankton community structure, especially the increase in importance of Bosmina in 1984 and 1985, may be related to the kokanee population cycle. When Bosmina were at their highest abundance during the study period, densities of kokanee were at their peak. Because kokanee apparently prefer Daphnia, a change in this competing species may have favored an increase in the smaller, less utilized (by kokanee) Bosmina. Hrbacek (1962), and Brooks and Dodson (1965) clearly demonstrated that predation plays a dominant role in maintaining plankton community structure Hall et al. (1970) concluded that vertebrate and invertebrate predation had profound effects on the diversity and size distribution of zooplankton, but only affected production at low nutrient levels. Kerfoot (1974) also stated a similar relationship between the abundance of Daphnia and smaller Clad-, Bosmina and Ceriodaphnia, in explaining the microfossil record of Frains Lake, Michigan.

Zooplankton populations in Libby Reservoir exhibit typical patterns found in most temperate lakes and reservoirs (Wetzel 1975), with maximumabundance in the spring and early summer, a decline throughout the summer and a slight increase in the fall (Figure 10). Daphnia abundances were greatest in the Canada area

<u>Bosmina</u>	1.1	9.3	6.7	0.4	4.9

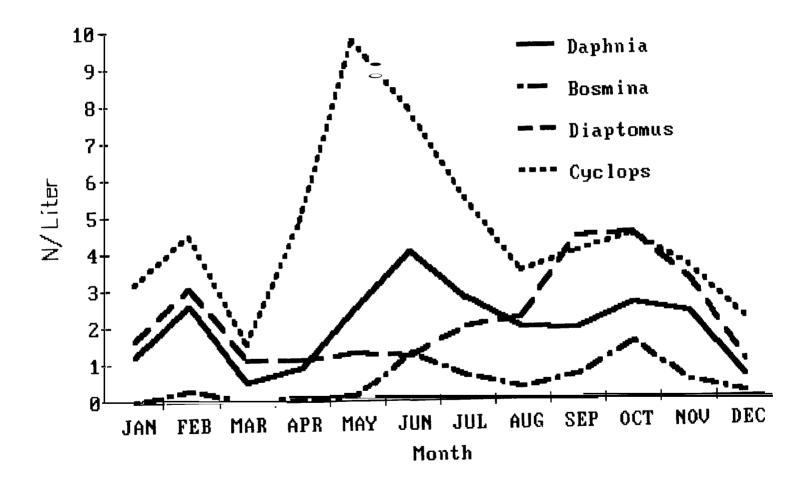

Figure 10. Seasonal abundance of the primary zooplankton genera in Libby Reservoir Density has been averaged for each month for all samples collected from 1983 through 1987.

for all years sampled, with the exception of 1984 when a February sample taken in the Termile area contained 4.57 <u>Daphnia</u> per liter (Appendix D, Tables Dl through D18). Peak mean densities of <u>Daphnia</u> ranged between 4.31 and 10.47/l in the Canada area, 1.03 to 7.35/l in the Rexford area, and 1.63 to 4.76/l in the Tenmile area for the five years of sampling (ibid). In general, <u>Daphnia</u> densities peaked during May or June for all three areas, <u>Cyclops</u> densities peaked during April through June, and <u>Diaptomus</u> densities peaked in the fall, from September through November (Appendix D, Tables Dl through D18).

Zooplankton densities varied by area and year: statistical differences appeared dependent on the genera of zooplankton. Daphnia and Diaptomus densities were statistically greater in the Canada area than the Tenmile area, but only Daphnia densities were greater in the Canada area than in the Rexford area (Table 15). Greater nutrient input, faster spring warmup and less kokanee predation in the Canada area relative to the other areas may account for the difference. Water temperature, changing food conditions, and increased activity or abundance of predators were listed by Threlkeld (1979) as a hypothesis to explain Daphnia seasonality.

Overall <u>Daphnia</u> densities statistically differed between areas, but not between years. <u>Bosmina, Diaptomus, Cyclops</u>, and <u>Epishura</u> densities did vary through the years of sampling, however, as indicated in Table 15. <u>Bosmina</u> densities were highly variable, with all but years 1984 and 1985, 1983 and 1987, and 1985 and 1987 differing from each other. For <u>Diaptomus</u>, 1984 was the only year that differed fron the rest; densities were lower in 1984 than all other years except 1987. <u>Cyclops</u> densities differed in 1983 and 1985 with densities in 1983 being the lowest of all years, all other year combinations were statistically similar. Because the sampling year in 1983 began in September (the project was first funded in May 1983), the large peak in <u>Cyclops</u> densities typically seen in May (Figure 10) was not detected. This bias probably accounts for the majority of the variation between 1983 and 1985.

While overall Daphnia densities did not statistically vary by year, the percent composition of Daphnia size classes did fluctuate (Figure 11). Notched box and whisker plots of the percent Daphnia in the 0.5- to 0.99-mm and 1.5- to 1.99-mm size class are presented in Appendix E, Figure Eland E2. The notches provideanapproximate 95 percent test of the null hypothesis that the true medians are equal (Chambers et al. 1983). From the plots it is apparent that the percent of small (0.5 to 0.99 mm) Daphnia was greatest in 1984 and 1985, when kokanee numbers were at their peak, and the lowest percent of large (1.5 to 1.99 mm) Daphnia also occured during 1984 and 1985. The implication is that kokanee are exerting size-selective pressure on the Daphnia Other authors have found size-selective fish population. predation as a major influence on zooplankton community structure (Werner and Hall 1974, zaret and Kerfoot 1975, Lynch 1979).

Table 15. Non parametric Tukey-type multiple comparisons for total zooplankton, <u>Daphnia</u>, and <u>Diaptomus</u> densities by study area and year. Between-area differences are indicatedby different numbers: more than one number indicates similarity to both groups.

Area	Total Zooplankton	<u>Daphnia</u>	Diaptomus
Tenmile	1,2	1	1
Rexford	1	1	1,2
Canada	2	2	2

Year	Total Zooplankton	Bosmina	Diaptomus	Cyclops	Epischura
1983	1	1,2	1	1	1,2
1984	1,2	3	2	1,2	1
1985	2	3,4	1	2	2
1986	1,2	2	1	1,2	1
1987	1,2	1,4	1,2	1,2	1

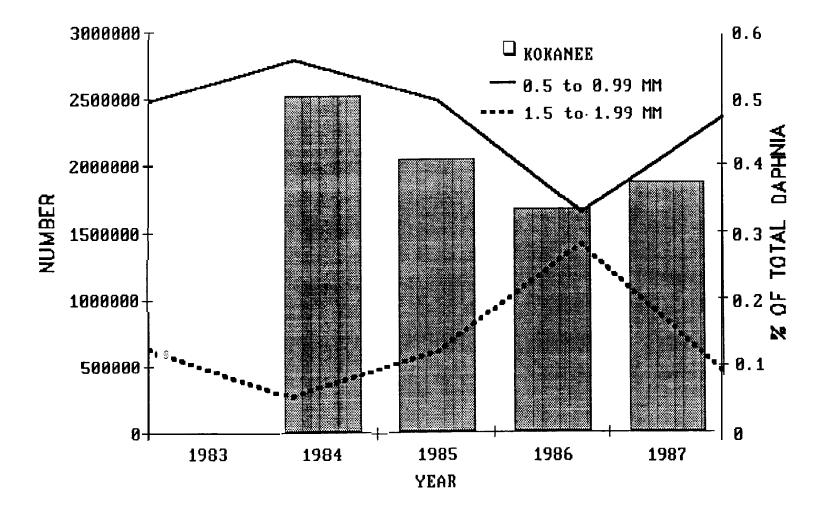

Figure 11. Comparison of estimated kokanee population size in Libby Reservoir and the relative percent of <u>daphnia</u> in the 0.5- to 0.00-mm and 1.5- to 1.99-mm size classes.

Results of our comparison of formalin-preserved zooplankton samples versus ethanol-preserved zooplankton samples indicated that no significant differences in mean length occurred (Table 16). Avery slight difference in mean length of <u>Daphnia</u> existed: the <u>Daphnia</u> preserved in the formalin measured an average of 1.09 mm while the <u>Daphnia</u> preserved in ethanol measured 1.05 mm. This difference is felt to be negligible; however, further shrinkage may occur if samples are not processed within 3.5 months and this should be recognized.

Vertical Distribution

From September 1983 through September 1987, 920 Schindler trap samples were collected from Libby Reservoir. In addition, 216 Schindler trap samples were collected as part of a 48-hour diel series, in which the plankton (0- to 30-m depths) and water quality profile (0- to 48-m depths) in the Rexford area were monitored every two hours on July 20 through July 22, 1986.

The following discussion refers to the tables supplied in Appendix F. All species of zooplankton in Libby Reservoir exhibited some level of varying vertical distribution throughout the year. Generally, during the spring and summer months, depths from 12 to 30 m contained the lowest densities of each type of zooplankton and the 3- to 6-m depths contained the highest densities. Between October and March, densities at depth became more uniform throught the water column. In all cases during the May through September period, densities found between the surface and 12 m were greater than densities found below 12 m.

The seasonal pattern of vertical distribution of <u>Daphnia</u> is presented in Figure 12. Shifts in the vertical distribution of zooplankton in Libby Reservoir detected by our daytime sampling are likely due to changes in water temperature and the depth of the euphotic zone and therefore availability of food. The relatively shallow depths (0 - 9 m) that zooplankton in Libby Reservoir seem to occupy during a majority of the spring and summer period may be a reflection of the annual turbidity cycle the reservoir experiences with refill. Zettler and Carter (1986) documented that many zooplankton species in Lake Temiskaming, Ontario-Quebec, displayed somewhat higher midday vertical distributions in turbid than in clear waters.

<u>Daphnia</u> exhibited a slight diel vertical migration pattern in the Rexford area during the summer of 1986 (Figure 13). A greater percentage of the <u>Daphnia</u> were found at the shallower depths (O-6 m) during late night and early morning hours than during daylight hours. The effect was most pronounced in the surface waters where 20 to 30 percent of the Daphnia were found during late night-early morning periods, but 0 to 10 percent were found during midafternoon periods. <u>Daphnia</u> densities were generally greatest at the 3-, 6-, and 9-m depths and densities from the 12- to 30-m depths were comparatively low and did not differ statistically. <u>Daphnia</u> apparently migrated to the surface during the late night

Table 16. Comparison of zooplanktonlengths in samples preserved with formalin and with 95 percent ethanol. Samples were collected at the Tenmile area on December 18, 1986 and analyzed on March 30 and 31, 1987. Data is presented by number / mean length / standard deviation.

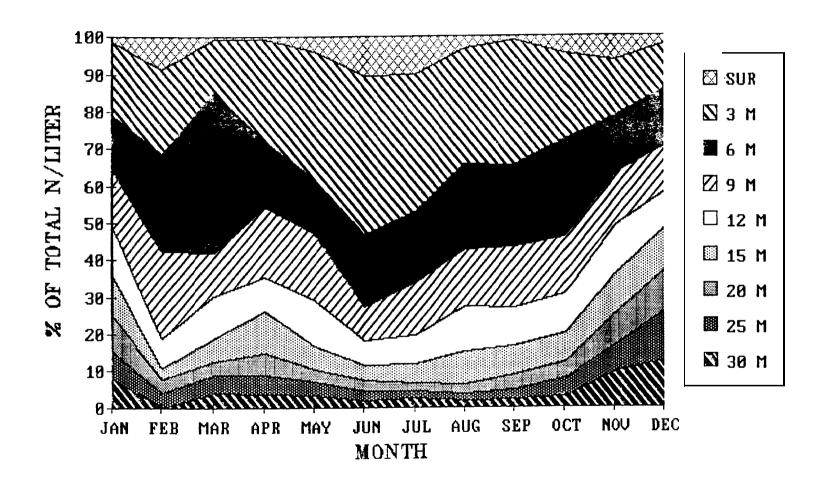

Figure 12. Seasonal vertical distribution of <u>Daphnia</u> in Libby Reservoir, all data combined, 1983 through 1987.

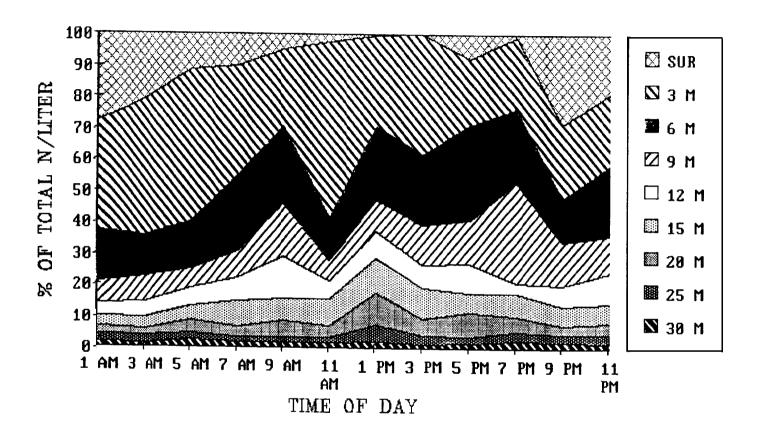

Figure 13. Diel vertical distribution of <u>Dapnnia</u> in the Rexfed area of Libby Reservoir, July 21, 1986.

and early morning hours. Euphotic zone depth ranged from 2 to 10 mm at the time of sampling. Water temperature averaged 10 C at 30 m, 160 C at 10 m and 20oC at the surface.

Three explanations for vertical migration of Daphnia are avoidance of sight feeding predators during daylight hours (Zaret and Suffern 1976), growth maximization by moving to cooler waters after feeding (the emergetic or demographic hypothesis proposed by McLaren [1974]), and migration timed to crop the daily peak of primary production (Enright 1977). Each of these hypothese could be applied to explain the diel migration of Daphnia illustrated in The increase in density at a depth of 3 m at 11:00 am Figure 13. was noted on both sampling days and may be an attempt to take advantage of the photosynthetic peak The increase in density at 9 m during the 7:00 pm aampling occurred when surface temperatures were 240C and the temperature at 9 m was 160C. Orcutt and Porter (1983) concluded that maximum fitness is achieved by Daphnia remaining at the warmest surface waters atalltimes, refuting McLaren's (1974) hypothesis. Conclusions as to the mechanism involved in <u>Daphnia</u> diel vertical migrations at Libby Reservoir are not possible, based on our sampling methods. However, this type of data has important implications, particularly when interpreting or applying zooplanktondata sets to dam operation.

TERTIARY PRODUCTION

FISH-

Methods

Rainbow and cutthroat trout field identifications were based on scale size, presence of basibranchial teeth, spotting pattern and presence of a red slash on each side of the jaw along the dentary. We recognize the difficulty in distinguishing between rainbow, cutthroat and their hybrid using morphometric characteristics as reported by Leary et al. (1983), and where appropriate have grouped the two species.

Abbreviations used throughout this report for the various species of Libby Reservoir are as follows: rainbow trout (RB), westslope cutthroat trout (WCT), rainbow x cutthroat hybrids (HB), bull trout (DV), kokanee salmon (KOK), mountain whitefish (MWF), burbot (LING), peamouth (CRC), northern sguawfish (NSQ), redside shiner(RSS), largescale sucker(CSU), longnose sucker(FSU), and yellow perch (YP).

Seasons

The year was stratified into four seasons based on reservoir operation and surface water temperature criteria for gillnetting:

- Winter (January -March), the reservoir was being drawn
 down, surface water temperatures dropped below 80C;
- Spring (April June), the reservoir was refilled, surface water temperatures increased to 9 - 130c;
- Summer (July- September), the reservoir was held at full pool, surface water temperatures increased to above 170c and;
- Fall (October December), drafting of the reservoir began, surface water temperature dropped to 13 900

Nearshore Zone Fish Abundance

Seasonal and annual changes in fish abundance within the nearshore zone were assessed using floating and sinking horizontal gill nets. These nets were 38.1-m long and 1.8-m deep and consisted of five equal panels of 19-, 25-, 32-, 38-, and 51-mm mesh.

One to seven "double-floating" (two ntes tied together end to end) and two sinking gill nets were set in the spring and fall. Nets were set perpendicular from the shoreline just before sunset and were retrieved shortly after sunrise. All fish were removed from the nets, and species, length, weight, sex and state of

maturity were recorded. Scales, stomach samples and a limited number of otoliths were collected for age and growth analysis.

A spring sinking and fall floating gillnetting series have been used by the MDFWP since 1975 to assess annual trends in fish abundance. These yearly sampling series were continued using criteria established by Huston et al. (1984). Numbers of fish caught per net between 1975 and 1982 were comparedby Hustonet al. (1984) by the Kruskal-Wallis ranking test, and were used in this report. Catch rates during the period from 1983 through1987 were log transformed and tested for significant differences at the five percent level using analysis of variance.

Limnetic Zone Fish Abundance

Vertical gill nets were used to assess the relative abundance and depth distribution of fish species in the limnetic zone of each area. An overnight set of four 45.7-m deep by 3.7-m wide vertical gill nets of mesh sizes 19, 25, 32 and 38 mm was made monthly in each area. Each net was marked at 1-m intervals. As the vertical nets were retrieved, fish were removed and depth of capture, species, length, weight, sex, and state of maturity were recorded, and scale samples and fish stomachs were collected. Relative abundance of the various fish species in the limnetic and nearshore zones were compared using vertical and horizontal gillnettingdata.

Results and Discussion

Nearshore Zone

In the period 1983 to 1987, 742 floating and 198 sinking gill nets were set, capturing 28,228 and 11,364 fish, respectively. A total of 13 species of fish were captured, three of which represented over 70 percent of the catch on most sampling dates.

Notable changes in the assemblage of fish species in Libby Reservoir have occurred since impoundment in 1972. species, kokanee and yellow perch, are present that did not occur in the Kootenai River prior to impoundment. Kokaneewerereleased into the reservoir from the Kootenay Trout Hatchery in British Columbia, and yellow perch may have dispersed into the reservoir from Murphy Lake (Huston et al. 1984). Peamouth and northern squawfishwererare in the Kootenai River before impoundment, but have increased in abundance in the reservoir. Mountain whitefish, rainbow trout, westslope cutthroat trout and redside shiner were all common in the Kootenai River before impoundment but have decreased in abundance since impoundment. Two predacious species, bull trout and burbot, were uncommon in the Kootenai River before impoundment, and subsequent gill net catches show no clear population trends. More detailed descriptions of changes in gill net catches since 1972 are given below.

Peamouth

Peamouth were considered by Huston et al. (1984) to be rare in the Kootenai River before incorribert. Since 1979 they have been the most abundant fish captured in the fall gillnetting series, with the exception of 1985 when kokanee were numerically dominant (Table 17 and Appendix G, Tables Gl - G13). Theupwardtrend in catch rate has been consistent over time, except between 1983 and 1985. During the 1985 sampling period, water temperature was 4.80C colder than average temperatures during fall sampling in previous years, and nets were set 32 days later Colderwatermay have caused peamouth to be farther offshore, or to be less active and therefore less vulnerable to gillnetting. If so, 1985 catches were not a valid indication of population decline. The population structure of the 1985 catch was composed of more distinct age classes than were present in other years (Figure 14). The much larger catch in 1987 was dominated by a single year class (Figure 15).

Increases in catch of peamouth between 1978 and 1982 were significant (p>0.01) by the Kruskal-Wallis ranking test (Huston et al. 1984), and increases between 1983 and 1987 were significant (p<0.05) by ANOVA.

Kokanee

Kokanee were the second most abundant fish captured in the fall gillnetting series (Table 17 and Appendix G, Tables Gl - Gl3). Fluctuations in catch rate occurred annually according to the strength of various year classes. The first captures of Kokanee were made in 1979. Large numbers of kokanee were caught in 1982, most of which were ascertained by Huston et al. (1984) to be the result of an accidental release of 250,000 fry in 1980 from the Kootenay Trout Hatchery in British Columbia. Reproduction by these fish resulted in the large spawning population in 1985 which consisted of a single size class (Figure 16). The smaller catch in 1986 consisted of two distinct size classes (Figure 17) spawned in 1983 and 1984.

Yellow Perch

Yellow perch were first caught in the spring sinking gill nets in 1982, and each year thereafter the catch rate increased (Table 18 and Appendix G, Tables Gl - Gl3). The annual increases after 1985 were statistically significant (p<0.05). The barren and heavily eroded shoreline of Libby Reservoir is unlike the debris or vegetation-covered substrate preferred by yellow perch for spawning (Scott and Crossman 1973). Based on the rate of increase of yellow perch since 1982, lack of spawning habitat does not yet appear to be limiting their abundance.

Mountain Whitefish

Mountain whitefish have shown a dramatic decline from their abundant status in the Kootenai River before impoundment to a

✓ Catches prior to 1984 reported by Huston et al. (1984).</sup>

b/ Addreviations explained in 'Methods."

 $^{{\}cal S}'$ Prior to 1984, very few hybrids were identified as such, although they were probably present in the samples.

Numbers of redside shiners were not recorded in 1975, al-

level of only 2.3 captures per sinking gill net set in the spring of 1987 (Table 18 and Appendix G, Tables Gl - Gl3). Catches in the initial years following impoundment were high, possibly due to the remnant population from the Kootenai River. Catches in sinking gill nets after 1978 were lower and more variable, ranging from 0.8 in 1985 to 5.8 fish per net in 1986. Lack of suitable spawning habitat in tributaries and the loss of the spawning substrate within the old Kootenai River channel may be the primary factors contributing to the decline of whitefish in Libby Reservoir.

Rainbow and Westslope Cutthroat Trout

Rainbow and westslope cutthroat trout captures in fall gill nets have both declined gradually since 1978 (Table 17 and Appendix G, Tables Gl - G13). High capture rates occurred for both species in the initial years of impoundment, although rainbow captures have been consistently greater than cutthroat captures. Kruskall-Wallis ranking tests showed a significant (p<0.01)</pre> decline in catch of both species from 1978 to 1982 (Huston et al. Analysis of variance of the catches in 1983 and 1987 also showed significant (p<0.05) differences. In both species, the causes for decline probably include reductions in planted stock, limited spawning habitat in tributary streams, and competition with the abundant planktivores in the reservoir. abundance may also be detrimentally affected by the reduction in redside shiner abundance, which McMullin (1979) found to be a primary prey item of rainbow trout in Libby Reservoir.

Redside Shiner

Redside shiner captures in fall gill nets indicated a decline similar to that shown by whitefish and trout species. Shiners, although restricted to slow water habitats, were common in the Kootenai River before impoundment. Captures in Libby Reservoir were high in the first years after impoundment, possibly dueto hold-overs from the Kootenai River, but since 1980 have averaged fewer than one fish per net in every year sampled (Table 17 and Appendix G, Tables Gl - G13). Spawning substrate for redside shiners, which consists of flooded vegetation, may have been available in the first years after impoundment and facilitated successful reproduction in those years. Extensive shoreline erosion in subsequent years probably eliminated suitable spawning substrate and may now be the primary factor limiting redside shiner abundance.

Bull Trout

Bull trout captures in the fall gillnetting series were low, probably because sampling coincided with the period in which adults were in the spawning tributaries. Captures in the spring varied between years without any statistically significant trend upward or downward (Table 18 and Appendix G, Tables Gl - Gl3). Mountain whitefish were found to be the primary food item in the stomachs of bull trout in Hungry Horse Reservoir (May et al. 1988)

and Flathead Lake (Leathe and Graham 1982). Huston et al. (1984) found the catch of bull trout in Libby Reservoir to increase and decrease with the catch of mountain whitefish, and this same trend has persisted from 1984 to 1987. This relationship may be coincidental for two reasons: 1) the changes in bull trout numbers from 1984 to 1987 were not statistically significant (p<0.05); and 2) bulltroutpopulations, being made up of several age classes, should have a delayed response to fluctuations in their prey base. Analyses of stomach contents of bull trout captured in Libby Reservoir between 1983 and 1987 show they are successfully utilizing most prey species other than mountain whitefish (Table 42).

Northern Squawfish

Northern squawfish were rare in the Kootenai River before impoundment, yet were one of the moreabundant fish in both spring and fall gill nets in the first years following impoundment (Table 17 and Appendix G, Tables Gl - Gl3). Spring catches have shown a modest decline over time, while fall catches have shown an increase from 2.3 fishpernet in 1975, to 9.1 fish in 1987.

Largescale Sucker

Largescale suckers were abundant in the Kootenai River before impoundment, and dominated catches in spring sinking gill nets set between 1975 and 1984 (Table 18 and Appendix G, Tables Gl - Gl3). Catches in 1986 and 1987 fell dramatically, and in both years were significantly lower (p<0.05) than in 1984 and 1985. Prior to 1986, spring sampling was done in the first or second week of June, and in 1986 and 1987 was done in the first week of May. This change in date of sampling probably accounts for the change in capture rate after 1985.

A single dominant size class of largescale suckers averaging about 375 mm comprised the 1984 and 1985 sinking gill net samples (Figure 18). The smaller catches in 1986 and 1987 consisted of several well defined size classes (Figure 19). The single size classes of 1984 and 1985 may have been spawning adults and the larger catch rates in 1984-85 than in 1986-87 may be the result of greater vulnerability of spawners that were enroute to shoreline or tributary spawning areas. Unlike the catches preceding 1986, the multiple size classes of 1986 and 1987 are assumed to be representative of the population structure of fish greater than 150 mm. The decline in catch rate in 1986 and 1987 is not considered to be a valid indication of the population trend.

Longnose sucker

Longnose suckers were uncommon in the Kootenai River before impoundment. In Libby Reservoir, longnose suckers were generally caught only in spring sinking gill nets. The highest catch rate was attained in 1976 when 11.1 fish per net was caught: the lowest catch rate was in 1986, when only 1.5 fish per net were caught (Table 18). The change in date of sampling after 1985 is assumed

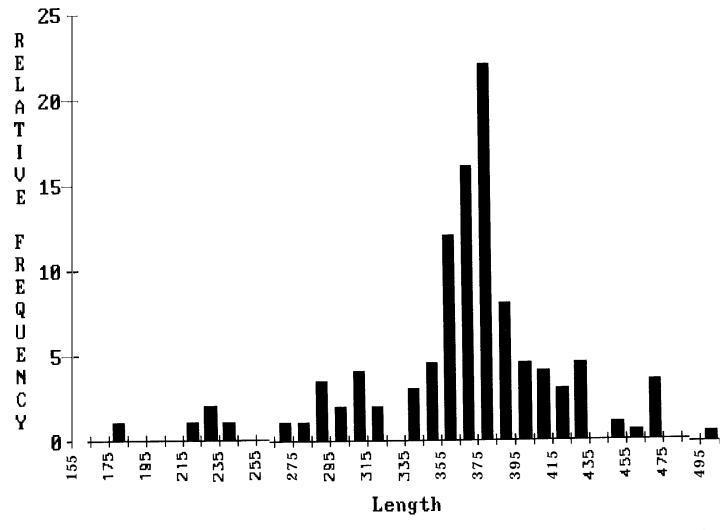

Figure 18. Length-frequency distribution of largescale suckers captured in spring gill nets in Libby Reservoir, 1984 and 1985.

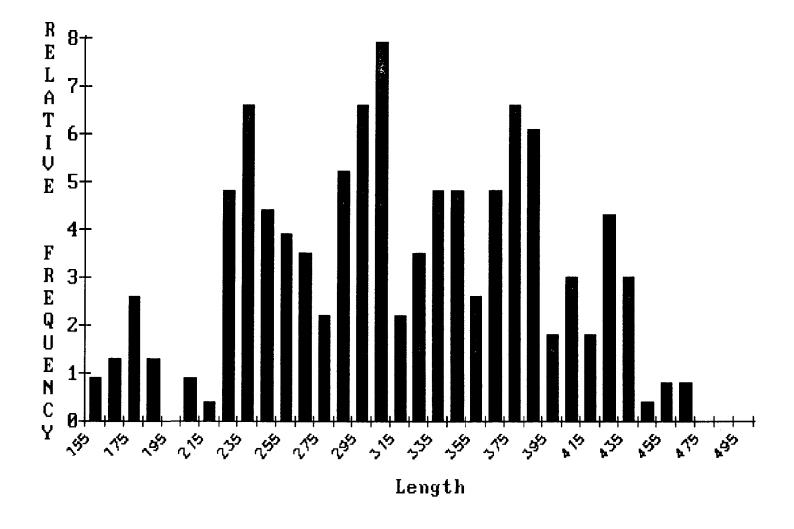

Figure 19. Length-frequency distribution of largescale suckers captured in spring gill nets in Libby Reservoir, 1986 and 1987.

to affect the catch oflongnose suckers just as it did the catch of largescale suckers, and is not considered an indication of decline in the population.

Burbot

Burbot were uncommon in the Kootenai River before impoundment. Catches in spring sinking gill nets were small in the first years following impoundment and have gradually increased to a high of 0.9 burbot pernetin 1987 (Table 18). Differences in catch rate at the 0.05 level of significance, exist only between the years of 1983 and 1987. Analyses of stomach contents of burbot caught between 1983 and 1987 have shown largescale suckers to be a heavily used prey item. The abundance of largescale suckers and increasing numbers of yellow perch (another important prey item) may have contributed to the increase of burbot.

Total Fish Abundance

The average total catch of fish in the floating gill nets set in the fall was fairly constant between 1975 and 1985. Large catches of 27.6 and 31.7 per net fish occurred in 1976 and 1982, respectively, while in other years the catch was consistently around 20 fish per net. In1986 the catch increased to 31.9 and in 1987 to 51.1 fish per net, solely due to increases in peamouth.

The average total catch of fish per sinking gill net set in the spring varied little between 1975 and 1980, ranging from 50 to 56.8 fish per net. After 1980, catches increased substantially until 1985 when catches peaked at 119.8 fish per net. catches in 1986 and 1987 dropped to half the size of the 1985 catch. The drop in total catch in 1986 and 1987 is not considered to be a valid indication of the population trend due to the change in sampling schedule described earlier. Catostomus spp. and peamouth accounted for most of the decline in 1986 and 1987. Both species are more susceptible to gillnetting in June than May because of spawning activity in June.

The relative frequencies of species captured in the spring sinking gillnetseries are shown in Figure 20. Five species of fish dominated the catch, comprising over 90 percent of the assemblage. Peamouth had the greatest relative abundance for all years, but since 1985 their relative abundance has decreased due to increasing numbers of northern squawfish and yellow perch. The relative percentage of Catastomus spp. in the catch remained relatively constant from 1984-1987, while the relative abundance of mountain whitefish varied greatly, ranging from less than 17 percent of the total catch in 1985 to 9 percent in 1986.

The relative frequencies of species caught in the floating gill net series set in the fall are given in Figure 21. Peamouth chubs had the highest relative abundance in all years except 1985 when they were displacedby a large year class of kokanee. The catch rate of northern squawfish remained relatively constant over

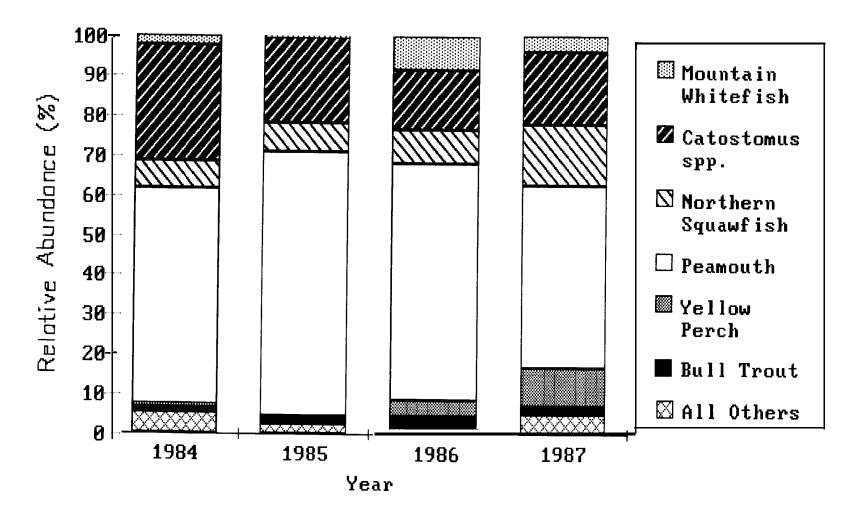

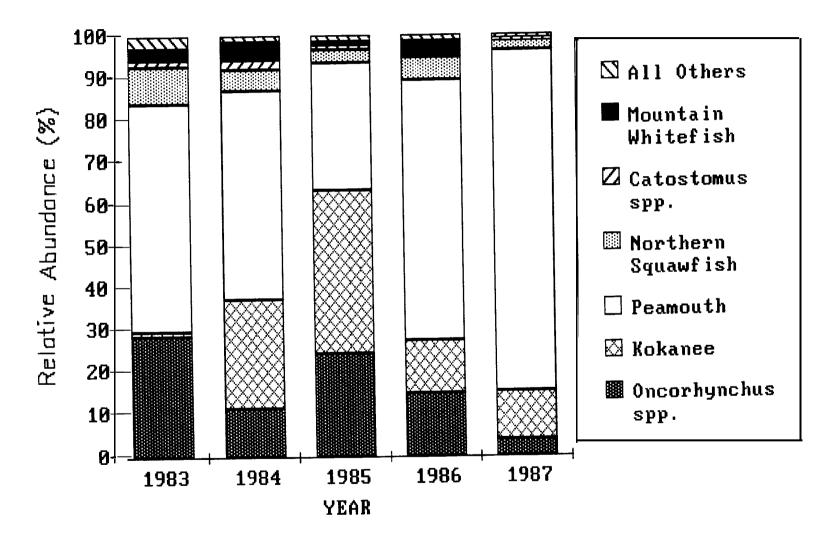

Figure 20 Relative abundances of fish species caught in sinking gill nets in the spring in Libby Reservoir, 1984 through 1987.

Figur: 21. Relative abundances of major fish species caught in floating gill nets set in the fall in Libby Reservoir, 1983 through 1987.

the sampling period, but its relative abundance declined due to the increase in peamouths. In addition, the relative abundance of Oncorhynchus trout species declined over the time period.

Changes in the assemblage of fish species in Libby Reservoir are similar to changes that have occurred in other reservoirs. The classic process of reservoir aging is initiated by a period of trophic disequilibrium as basin filling begins, and is eventually followed by a period of equilibrium (Kimmel and Groeger 1986). Disequilibrium is characterized by "trophic upsurge and depression" (Baranow 1961). Fluctuations in fish populations occur during the disequilibrium phase, but usually stabilize within 5 to 10 years (Kimmel and Groeger 1986). Trout species and mountain whitefish, common in the Kootenai River and in gill net catches immediately after impoundment, have declined since 1982. Jenkins and Morais (1971) found sport fish harvest to be negatively correlated with reservoir age in over 100 North American reservoirs studied. They also found reservoir age to have no affect on total fish standing stock due to increases in clupeid abundance. Total standing stock in Libby Reservoir as indicated by fall floating gill net captures is increasing, and is due to increases in peamouth chubs as well as kokanee, both of which utilize limnetic production. The numerical dominance of these pelagic species became apparent in 1982, 10 years after impoundment, The upward trend in abundance of peamouths, kokanee and yellow perch will probably be controlled by competition for the plankton resource.

Limnetic Zone

Species composition of vertical gill net catches in the Tenmile and Rexford areas were more similar to each other than they were to catches from the Canadianportionofthe reservoir (Table 19 and Appendix H, Tables Hl - H6). At the north end of the reservoir, peamouths comprised an average of 68 percent of the catch from 1984 to 1987, while kokanee comprised only 13 percent of the catch. In the Tenmile and Rexford areas, peamouth comprised an average of 10 percent and 27 percent, respectively, from 1983 to 1987, while kokanee comprised 82 percent and 60 percent of the catch, respectively.

In 1983, Oncorhynchus trout and bull trout comprised up to 25 percent of the catch in the Tenmile and Rexford areas, but diminished in most cases to less than one percent of the catch in all subsequent years. Vertical gillnetting was not done in Canada in 1983. After 1983, Oncorhynchus trout, mountain whitefish, Catostomus spp. and northern sguawfish had a greater relative abundance in Canada than either the Termile or Rexford areas. The assemblage of fish in the Canadian area more closely resembles that which is present in the KootenaiRiver.

Table 19. Relative abundance of fish species captured in vertical gill nets in three sampling areas in Libby Reservoir, 1983 through 1987.

HYDROACOUSTIC ESTITMATE OF KOKANEE

Methods

Kokanee abundance was estimated each year from 1984-1987 using hydroacoustics. Sampling was conducted during moonless nights in August. Visual isolation during moonless nights results in an even dispersal of kokanee thereby increasing the reliability of the technique (Hanzel 1984).

A Honda Sitex depth recorder (Model HE 356A) with a transducer beam angle of 10 degrees and frequency of 220 mHz was used. Cone width was assumed to be consistent with the 10-degree beam angle. Thirty-eight-covering four discrete reservoir areas were surveyed. After July 1985, distance traveled along each transect was measured by a knotmeter. Transect sampling began approximately one hour after sundown using compass bearings and (after 1985) by steering toward flashers placed at the end of each transect. Reservoir sonar sampling was completed within two to four nights, generally with one area (8-10 transects) completed each night.

All targets within interval were counted. The number of kokanee per transect was calculated using vertical gill net species composition proportions. Numbers ofkokaneeper 1,000 m were calculated for each depth interval. These estimates were then converted to numbers per area and expanded to total surface area using methods and assumptions explained by Shepard (1985).

Results and Discussion

Sonar transect lengths were 73 to 76 km, with the exception of the 1986 estimate where the total measured length of the transects was 90.5 km (Appendix I, Tables II - 14). The area exhibiting the mostvariationintransect lengths andvolumes was Tenmile. The cause of the extra length in 1986 could be wind-induced drift as the transects were sampled, or recording error. In any case, numbers in 1986, at Tenmile and for the total, were lowest of any of the years sampled

Since their introduction by Canadian fisheries personnel throughout the 1970's, the kokanee population in Libby Reservoir has experienced cyclic population dynamics. Kokanee in Libby Reservoir spawn as 2[†] year old fish and their pattern of abundance is apparently related to a strong 1979 and/or 1981 year class. The pattern is such that every third kokanee year class is "strong" and is followed by two "weaker" year classes. Although this abundance trend is apparently stabilizing, it still dominates kokanee population dynamics in Libby Reservoir. Because the hydroacoustic gear we have used does not have the capability to differentiate size and therefore age class of kokanee, interpretation of our population estimate necessitates an understandingofthe kokanee population pattern. Our population

estimates are presumed to includeprimarilyage 1+ and 2+ fish, although the possibility exists that some age 0+ fish were included in the estimate.

In 1984, we estimated that Libby Reservoir contained the highest total numbers of kokanee, 2.5 million fish, primarily composed of a very strong 1983 year class (Table 20). The 1985 estimate was smaller by approximately 500,000 fish. Kokanee numbers in 1986, immediately after the largest (1985) year class spawned, reached the lowest value of any year yet measured. This estimate includes the two 'weakest' year classes forthatperiod, the 1984 and 1985 young-of-the-year.

For comparison, Rieman and Bowler (1980) estimated that kokanee numbers in Pend Oreille Lake, Idaho, ranged from 5to 12 million fish between 1974 and 1978. Pend Oreille is the largest lake in Idaho with a surface area of 383 km². Interestingly, the kokanee population in Fend Oreille apparently stabilized in 1976 and 1977 before declining in 1978 (Rieman and Bowler 1980).

Estimated densities of kokanee in the Libby Reservoir during August differed by area and year (Table 21). In two of the four years, 1985 and 1986, Peck Gulch had the highest densities, 276.5 and 443.8 fish/ha, respectively. For all four years, the Canada area had the lowest densities, ranging from 5.4 to 17.3 kokanee per hectare.

FISH AGE AND GROWIH

Methods

Fish collected in Libby Reservoir and its tributaries were measured as total length (TL) and weighed to the nearest gram (g). Scales were removed from fish in an area abovethelateral line and between the dorsal and anal fins following Lagler (1956). Cellulose acetate impressions of the scales were examined at 48% or 72% magnification using a microfiche reader Distances were measured in a straight line from the focus to the annuli and midanterior margin of the scales using a millimeter ruler

Age and growth information was analyzed using the FIRE 1 computer program (Hesse 1977) as modified by Montana Department of Fish Wildlife and Parks personnel. Age was assigned based on interpretation of annulus formation on scales (Jearld 1983). Body length-scale radius relationships were describedusing log-log plots and the Monastersky technique.

Otoliths from a limited number of trout, burbot and salmon were analyzed by Dr. Ed Brothers (EFS consultants, Ithaca, New York) to validate aging by scales and to provide additional information on seasonal and differential growth of fish in the reservoir. Method of analysis was similartothatreportedby Brothers et al. (1976) and is described in detail by May et al. (1988).

b/ Number/area values that are significantly different are indicated by different capital letters.

Results and Discussion

Fish growth is influenced by many factors (Ploskey 1986, Piper et al. 1982). Water temperature and other habitat characteristics (Brett 1971, Everhart and Youngs 1981), food availability and nutrition (Wolfert and Miller 1978, Piper et al. 1982), and competition (Calhoun 1966, Carlander 1969, Christie 1974, Schiavone 1985) have all been documented to affect fish growth. Kokanee exhibit density-dependent growth (Johnson 1965, Foerster 1968) and effects of reservoir operation on area or volume of the reservoir may influence population densities (Jenkins 1970, Aggus 1979). However, any effects of reservoir operation on growth are confounded by influences of temperature, competition, food availability and habitat characteristics.

Rainbow trout

Age determination and scale measurements were performed on 417 rainbow trout captured in Libby Reservoir. The intercept of the scale radius vs. body length regression line was 16.14 mm with a slope of 0.62 and a correlation coefficient of 0.84.

Analysis of scales showed that there were distinct transition zones of growth where circuli became wider, finer and very uniform. These were believed to be zones formed following emigration from natal streams to the reservoir. Annuli formed during growth in the reservoir were recognized by a periodic pattern in the fall and winter where spacing between circuli became less. Growth after the firstyearwas slowerandannual zones were more difficult to interpret. An explanation for this could be slowing oftroutgrowth due to maturation or change in food habits (Mueller and Rockett 1980; Hensler 1987).

Five distinct migration classes (trout that emigrated from natal streams to the reservoir at ages 0+, 1+, 2+, 3+, and 4+) were determined to exist in the samples based on scale aging techniques (Table 22). Migration classes 0, I and II made up the vast majority of the sample (44, 38, and 14 percent, respectively). Migration classes III and IV had small sample sizes (3 and 2, respectively) and were therefore not included in the following discussion.

Migration class was apparently related to size at age. Trout migrating at younger ages had a growth advantage over older migrants, due to the difference between growth in the reservoir versus the stream. Rainbow trout migrating as fry were the largest-sized class as one-year-olds, followed in size by migration classes I and II. As two-year-olds, migration class I trout were similar in size to the trout migrating as fry. At age three, earlier migrants averaged 55 mm longer than class II; the difference was 34 mm at age four, and by age five all migration classes were similar in length.

Mean lengths at annuli for stream residence of trout migrating as one- and two-year-olds were greater than those found by Huston et al. (1984) between 1972 and 1982. Lengths at annuli during reservoir life were slightly lower for trout in this study until age four, at which point they were similar. It is likely that this is related to the drop in abundance of redside shiners, at one time an important food item for rainbow trout over 330 mm (Huston et al. 1984, McMullin 1979). Between 1983 and 1987, rainbow trout fed largely on zooplankton and insects and very little on fish (see section on Fish Food Habits). Evidence suggesting that this change in food habits may have altered growth rates is given by Helsler (1987) who studied rainbow trout in Montana lakes and found that fish that relied heavilyondaphnids grew more slowly after 350 mm TL than those that switched to larger food items.

Several authors have noted the possibility of scale aging being inaccurate (Beamish and McFarlane 1983, Boyce 1985, Hubert et al. 1987). Beamish and McFarlane stated that validation is absolutely necessary for accurate age determination and reported that if known age fish were not available, validation by different techniques should be considered. Hubert et al. (1987) found that aging with scales and otoliths in combination yielded accurate results.

For this study, findings based on otolith analysis were similar to those from scales. Otolith analysis determined that migration class I and II fish were 108 mm and 147 mm TL, respectively, at annuli formed prior to emigration to the reservoir in 1985 (Table 23). These back-calculated lengths were about 10 percent smaller than those derived from scale analysis, where migration class I and II fish were 120 mm and 166 mm TL, respectively, at annuli formed prior to emigration in 1985 (subset of data in Table 22).

Brothers (1987) analyzed rainbow trout otoliths from Libby Reservoir and found there to be a transition zone of growth between stream and reservoir. He found that this transition may be abrupt, with the increments becoming wider and more uniform, or else the transition is more gradual with an intermediate area of poorly defined increments before reservoir growth. His results indicate that fish enter the reservoir in the last week of May through the first two weeks of June.

Monthly increments of growth derived from otoliths indicated that migration class I fish grew at a faster rate than migration class II fishduringtheir first year in the reservoir, but that both migration classes grew fastest from April to June (Table 23). Migration class I fish grew 51 mm/month between April and June and slowed to 17 mm in October: migration class II fish grew 36 mm/month from April to June and slowed to 15 mm in October.

Westslope Cutthroat Trout

Age and growth determinations were made on 354 westslope cutthroat trout collected from Libby Reservoir from 1984 through 1987. The intercept of the scale radius-body length regression line was 15.08 mm with a slope of 0.66 and a correlation coefficient of 0.90.

Based on scale analysis, the sample of captured cutthroat trout consisted of migration classes 0, I, II, and III, with migration classes II and III making up the majority of the sample (67 percent, and 22 percent, respectively) (Table 24). Fish in all migration classes nearly doubled in length from time of emigration to the reservoir to the first annulus formation in the reservoir. Lengths at first reservoir annulus were similar for migration classes I, II, and III (302 mm, 303 mm, and 309 mm, respectively). Migration class 0 put on most growth during the second growing season in the reservoir. Migration classes 0 and I maintained a length advantage over other classes until age five at which point all classes were similar in length,

Lengths at first reservoir annulus averaged about 75 mm TL grater for class I migrants than those reported by Huston et. al. (1984) between 1972 and 1982. Cutthroat trout in this study maintained that advantage through age three. Similarly, lengths for migration classes II and III were greater in this study than those found by Huston etal., but the size differences were much less (10 mm and 7 mm, respectively).

A possible explanation for cutthroat trout being more similar in lengths at age than was seen in rainbowtroutmaybe found in their respective food habits. Cutthroat trout tend to feed more heavily on daphnids and aquatic and terrestrial insects (McMullin 1979). Therefore, a decrease in the redside shiner population would not adversely affect cutthroat trout as it would rainbows.

Lengths of migration classes II and III cutthroat trout also were higher than those reported for Hungry Horse Reservoir (May et. al. 1988) and for Flathead Lake (Leathe and Graham 1982). This may reflect higher productivity in the Kootenai River system than in the Flathead system.

Rainbow X Cutthroat Hybrids

Age determination and scale measurements were performed on 321 hybrid trout. The intercept for body length-scale radius regression line was 16.14 with a slope of 0.63 and a correlation coefficient of 0.84. In addition, otoliths from 57 hybrids were used to assess monthly growth.

Analysis of scales showed the sample to consist of migration classes I, II, III, and IV. Migration class II made up the majority of hybrids captured (59 percent) while the others were similar and ranged from 12 to 15 percent (Table 25). Back-

calculated lengths at annuli were very similar to both rainbow trout and cutthroat trout. All migration classes were approximately 300 mm TL after the first growing season in the reservoir. Migration classes 0 and I maintained a growth advantage over other classes that was achieved the firstyearin the reservoir and lasted through year five.

Growth increments were similar to those of cutthroat trout and rainbow trout, suggesting that in Libby reservoir, life histories of the different trout types are similar. Greatest growth of hybrid trout was achieved in the first year of reservoir life. Growth increments decreased from 189 mm TL to 130 mm TL as age at migration increased. Otoliths were used to determine monthly growth rates of age 2+ hybrid trout during their first summer in the reservoir in 1986. Rack calculation of otoliths revealed that fish averaged 173 mm TL upon entering the reservoir in mid June, and grew by increments of 32 mm, 30 mm and 27 mm during subsequent 30-day intervals.

Kokanee

Otolith measurements from a sample of 100 kokaneecaptured between 1984 and 1987 were analyzed to determine monthly and annual lengths and growth rates. Because the majority of kokanee in Libby Reservoir spawn at age 2+ and sample sizes of 3+ and 4+ kokanee were low (two and one, respectively), discussion will be limited to age classes 1 and 2.

Age 2+ kokanee showed the greatest second year growth in1986 (141 mm), followed by 1983 (125 mm) and1985 (103 mm) (Table 26). Age 1+ kokanee showed similardifferences inannuallengthsamong years, with greatest growth occurring in 1983 and 1986, and least growth in 1985 (Table 27). It has been well documented that salmon populations exhibit density-dependent growth (Johnson 1965, Foerster 1968, Goodlad et al. 1974). The year when both age 1+ and 2+ kokanee growth declined in Libby Reservoir (1985) was a year of relatively high density (Table 20); conversely, growth was relatively high in 1986 when total numbers were lower. It is possible that high numbers of both age classes exert a density-dependent pressure and thereby decrease growth.

Otoliths were used to determine monthly growth rates for age 2+ kokanee (Table 28). For the period June through October, growth increments were highest in the June-July interval and lowest in the August-September or September-October interval. The high rates in June through July correspond with blooms of Daphnia in the reservoir and their association with water temperatures preferred by kokanee. Two-year-old kokanee captured in 1986 showed greatest growth in the August-September interval.

Bull Trout

Age determinations and scale measurements were made on 78 bull trout from 1985 through 1987. The intercept of the body length-scale radius regression line was 12.33 mm with a slope of 0.802 and a correlation coefficient of 0.80.

Three-, four- and five-year-olds comprised the majority of the catch of bull trout during the study period (21 percent, 38 percent, and 28 percent, respectively) (Table 29). Captured bull trout comprised three migration classes. The highest percentage of the catch was from migration classes II and III (59 percent and 38 percent, respectively). Composition of migration classes was similar to that found in Libby Reservoir from 1972 through 1982 by Huston et al. (1984).

Growth among all migration classes of bull trout was similar for the first year in the reservoir (126 mm, 110 mm, and 107 mm for migration classes II, III, and IV, respectively). First year growth increments in this study were greater than those reported by Huston et al. (1984) for Libby Reservoir from 1972 through 1982, by Leathe and Graham (1982) for Flathead Lake, or May et al. (1988) for Hungry Horse Reservoir. In addition, bull trout in Libby Reservoir exhibited greater growth up to age four than these other Montana studies, at which point growth was comparable. This suggests that there may be more readily available food organisms for smaller bull trout in Libby Reservoir but that those items are not enough to maintain the growth advantage for larger fish. Carlander (1969) noted that the intermediate-size bull trout (130 mm to 380 mm) fed most heavily on a spawning population of salmon and that kokanee were the principle food of bull trout in some Idaholakes.

Growth of migration class II bull trout to first annulus in the reservoir was greater than growth of migration classes III and IV, although migration class IV had a sample size of only two. This growth advantage was also carried up to the sixth year of life. Growth increments within the reservoir, although, were greater for migration class III than for migration class II and it appears likely that if continued for several more years, the length advantage gained by migration class II would diminish.

This pattern is considerably different than bull trout growth reported for Hungry Horse Reservoir (May et al. 1988). Growth increments of migration classes II and III in Hungry Horse Reservoir remained similar and stable for the first five years of life including the first year of reservoir life. Growth increments for migration classes II and III increased by only 18 mm and 11 mm, respectively, between last year of stream growth and first year of reservoir growth. Greatest growth was at age five for migration class II fish and age six for migration class III fish. Once again it appears as though upon entering the reservoir, some feeding advantage was gained in Libby Reservoir relative to the other areas noted above.

Mountain Whitefish

Age determination and scale measurements were performed on 168 mountain whitefish. The intercept of the body length-scale radius regression line was 12.25 mm with a slope of 0.709 and a correlation coefficient of 0.88.

Huston et al. (1984) reportedthatmountainwhitefish fry do not rear intributariesbutmovedirectlyto Libby Reservoir after hatching. This is consistent with the scale analysis, which showed greatest growth occurring in the first year of life, presumably corresponding to initial growth in the reservoir. Lengths at annuli continually decreased afterthattime (Table 30).

These results are comparable to those reported by Hustonet al. (1984) except that length at the first annulus was higher in this study. In addition, lengths at annuli for mountain white fish in Libby Reservoir were greater than those of populations found in other Montana lakes (Carlander 1969).

Burbot

Otoliths from 56 burbot collected in Libby Reservoir were utilized for age and growth analysis. A summary of the aging data is shown in Figure 22 and Table 31. No back-calculation of ages wasattemptedduetothepresence of "false" annuli and difficulty of measurement Brothers (1987) noted that although the annular marks were not rigorously validated, microstructural examination revealed the presence of seasonal growth patternsconsistentwith the age interpretation represented in Figure 22 and Table 31.

Sampled burbot ranged between 3 and 11 years old, with the mode at age 5. Corresponding lengths rangedbetween 269 mm and 1,003 mm TL. These lengths at age are smaller than those reported by Hustonet al. (1984) for fishcapturedbetween1975 and1980. There was high variability in lengths at age because times of capture includedallseasons.

Northern Squawfish

Scales from 17 northern squawfish were used for age and growth analysis. The scale radius-body length regression line intercept was 5.45 mm with a slope of 0.872 and correlation coefficient of 0.96. Growth increments gradually decreased after a high in the first year in the reservoir (Table 32). Year six was an exception in that it was about double the adjacent years, and was therefore probably an artifact of the low sample size. Annular lengths were all considerably greater than those reported for other Montana lakes and reservoirs (Carlander 1969). Because of low sample size these data should be interpreted with caution.

Peamouth chub

A small sample of scales (19) from peamouth chubs captured in Libby Reservoir was analyzed for age andgrowth (Table 33). The intercept of the scale radius-bodylengthregressionlinewas 9.92 mm with a slope of 0.69 and a correlation coefficient of 0.89.

Growth was greatest in the first three years of life, gradually decreasing with age. The growth increment between ages six and seven maybe an artifact of low sample size. Carlander (1969) reported annular lengths for peamouth chubs from other Montana lakes including Flathead lake, all of which were lower than the Libby Reservoir sample. Althoughthesedata should be interpreted with caution, the large size exhibited by peamouth chubs caught in gill nets in Libby Reservoir leads ustobelieve that the actual growth ofthisspeciesisoutstandingand likely mirrors their growth as determined by scale analysis.

FISH FOOD HABITS

Methods

Stomachs of various fish species capturedingillnets from 1983 through 1987 were collected and emptied into labeled plastic vials with a formalin preservative (prior to fall 1986) or with a 95 percent ethanol solution (after fall 1986). Stomach contents were sorted into taxonomic groups, counted and weighed. Subsampling was used when analyzing zooplankton and other abundant, small food items. Wet weights of all food categories except zooplankton were measured to the nearest 0.001 g after removing excess water by blotting.

The majority of zooplankton ingested by fish were fragmented, identifiable bodypartswereusedtoestimatethenumberof each genus within each stomach In the earliest samples (summer 1983), lengths of Bosmina spp., Diaptomus spp., Epishura spp. and Cyclops spp. were estimated as 0.3, 0.7, 1.2 and 0.5 mm, respectively, based on average lengths found in zooplankton collections at the time fish stomachs were sampled. Beginning in fall 1983, lengths were determined directly from stomach samples. Dry weights of these zooplankton were estimated using lengthweight regressions presented by Bottrell et al. 1976. All dry weights were converted into wet weights using a multiplication factor of 10. This multiplication factor is applicable for wet weights between 10 and 300 mg (Bottrell et al. 1976), the range most frequently found in Libby Reservoir. We assumed an average length of 6 mm for all Leptodora spp. and used this length to enter length-weight tables developed by Cummins et al. (1969) to estimate the wet weights of Leptodora spp. For stomachs collected in summer 1983, body lengths of Daphnia Spp. were estimated using measurements of the post-abdominal claw following methods presented by Leathe and Graham (1982). Beginning in fall 1983, Daphnia spp. body lengths were measured directly from stomach samples.

Species and size selection of <u>Daphnia</u> were expressed using Ivlevs (1961) electivity index as presented by Leathe and Graham (1981). The index ranges from -1 (avoidance of a food item) to +1 (positive selection of a food item). A value of zero represents a food item that has the same composition in the environment and the fish.

An index of relative importance (IRI) was calculated to estimate the importance of particular food items in the diet (George and Hadley 1979). The IRI is the arithmetic mean of the number, frequency of occurrence, andweightofa food item in the diet, expressed as a percentage. IRI values range from zero to 100, with a value of 100 indicating exclusive use of a food item. Frequency of occurrence and weight data were used to calculate IRI's for insect parts, algae, and debris.

The Shoener overlap index (Shoener 1970) was used to determine potential dietary overlap between species. The Shoener index gives values from zero (no overlap) to one (complete overlap).

Results and Discussion

A total of 2,494 fish stomachs from Libby Reservoir were collected and analyzed for food habits from 1983 through 1987 (Table 34). Empty stomachs (475) were not used in the analyses. In addition, stomachs from all geographic areas were used to insure that a complete sample was taken from the entire reservoir.

Kokanee

Stomachs from 386 kokanee captured between 1983 through 1987 were used in food habits analysis (Table 35). In all years, zooplankton were the most important food items forkokaneesalmon. Index of Relative Importance (IRI) values ranged from 92 to 98 between 1983 and 1987.

<u>Daphnia</u> were the most important food forkokaneewithrespect to zooplankton utilization Importance values ranged from a low of 59 in 1985 to a high of 96 in 1987. The copepods <u>Diaptomus</u> were next in importance and never comprised more than 29 percent of the diet of kokanee. The other food items were primarily dipteran larvae and pupae. The food habits of kokanee in Libby Reservoir are similar to those in other lakes (Finnel and Reed 1969, Leathe and Graham 1981, Schneidervin and Hubert 1987).

Monthly IRI's againshowedtheimportance of zooplankton in the diet of kokanee (Table 36). <u>Daphnia</u> species were the most important food items for all months except February when <u>Diaptomus</u> became the most important. <u>Diaptomus</u> was also important as a secondary food sourcebetween December and April. <u>Epischura</u>, a large copepod, was important sporadically throughout the summer and fall months.

Table 34. Number of storacts collected for food habits analyses from three areas of Libby Reservoir from 1983 through 1987. Lengths indicated for trout (<30, >30) are in millimeters.

<u>Daphnia</u> IRI values were extremely high relative to their relative abundance in Libby Reservoir, which suggests that kokanee are specific as to the type of organisms on which they feed. Speciesand size selection by kokanee has been documented by other investigators (Finnel and Reed 1969, Leathe and Graham 1981, Schneidervin and Hubert 1987). During this study, the density of large <u>Daphnia</u> taken by kokanee showed an inverse relationship to the population density of kokanee in the reservoir (refer to Figure 10). It was previously shown that kokanee may exert pressure on <u>Daphnia</u> populations that could lead to increased densities of smaller plankters. For this reason, potential size-specific selection on Daphnia by kokanee was analyzed.

Size selectivity of <u>Daphnia</u> by kokanee appeared to change throughout the seasons (<u>Table 37</u>). Selection for the larger <u>Daphnia</u> increased from winter through summer and then decreased again in the fall. Selectivity index values indicated that selection was primarily for those <u>Daphnia</u> greater than 1.49 mm in all seasons (<u>Table 38</u>) and is <u>similartothose</u> forkokaneein Flathead Lake (<u>Leathe and Graham 1981</u>). The avoidance values for the size class >2.0 mm during winter and spring months is unexplainable except that it may be due to sampling error.

Oncorhynchus trout species

Stomachs from 1,080 Oncorhynchus trout (westslope cutthroat, rainbow, and cutthroat X rainbow hybrids) captured in Libby Reservoir from 1983 through 1987 were examined to determine their food habits. Over 90 percent of the stomachs analyzed contained food items. All trout were combined because of the difficulty to positively identify the species in the field. In addition, trout species in Libby Reservoir have similar food habits (McMullin 1979, Huston et al.1984, Chisholm and Fraley1986). Trout were also separated by size class (trout <330 mm TL and trout >330 mm TL) as done by McMullin (1979) because of the potential for food preference differences between the sizes.

The diet of trout in Libby Reservoir was similar for all years except 1987 (Table 39). In most years, terrestrial and aquatic insects comprised the majority of the food for all size classes. Trends in feeding preference were also similar for all sizes of trout. Feeding on zooplankton decreased in 1985 and utilization of terrestrial and aquatic invert&rates increased. In addition, zooplankton was absent from the diets of both size classes of trout in 1987. The reason for the lack of zooplankton is not fully understood. As was shownpreviously, thedensityoflarger Daphnia (the primary zooplankton taken by trout) was considerably lower in 1987 than in 1986. Because of this, thetroutmayhave switchedtoa more available foodsource.

There was some seasonal variation in the food habits of trout in Libby Reservoir. This variation was closely related to availability of food items in the reservoir. Zooplankton were most important during the winter months, followed by aquatic

insects (Table 40). Inthespring, there was a considerable shift away from zooplankton to aquatic and terrestrial invertebrates. Coleopterans and dipterans, which showed peak abundances in emergence traps and surface insect tows during spring months, had the highest IRI's. As emergence of dipterans subsided in the summer, terrestrial invertebrates, especially flying ants, became the food of choice. In October and November, zooplankton and terrestrial and aquatic invertebrates were utilized comparably.

Mountain Whitefish

Stomachs from 225 mountain whitefish captured in Libby Reservoir from 1983 through 1987 were used to determine food habits. There was littlevariationin foodhabits among seasons for the whitefish. Daphnia were the most important food items during all seasons (Table 41). There was some variation in the size of Daphnia utilized. The mean length of Daphnia eaten in the fall was considerably greater than in all other seasons which had similar mean lengths. The reason for the increase in size of ingested Daphnia is likely due to a progression in growth of the planktor throughout the year. The greatest densities of larger Daphnia coincide with their utilization by mountain whitefish.

Aquatic and terrestrial invertebrates made up the majority of the remaining food items in all but the winter months. Carlander (1969) suggested that because terrestrial and aquatic insects were the primary food source for mountain whitefish, the utilization of zooplankton may indicate scarcity of the larger invertebrates. Food habits of mountain whitefish in Libby Reservoir were similar to those found in Flathead Lake (Leathe and Graham 1981) and in Hungry Horse Reservoir (May et al. 1988).

Bull Trout

Stomachs from 162 bull trout captured in Libby Reservoir from 1983 through 1987 were examined to determine their feeding habits. Fish species were the most important food items for bull trout throughout the year with a combined Index of Relative Importance value of 65 (Table 42). Fish species contributed to more than 99 percentofthetotal biomass ingested by bull trout. Index values were high for terrestrial and aquatic invertebrates in the spring and summer. Likely reasons forthehighvalues maybe due to an artificial inflation of the IRI from high frequency of occurrence and numeric parameters.

Hull trout ingested at least 10 different species of fish found in the reservoir. Collectively, salmonids were the most importantspeciesconsumed. Kokanee appeared to be the species of most importance to bull trout followed by <u>Oncorhynchus</u> trout species, largescale suckers, and peamouths. The only species not taken by bull trout were burbot and bull trout.

The type of prey taken by bull trout in Libby Reservoir is quite different than that reported for other waters. Leathe and Graham (1981) found that three speciesofwhitefishwereimportant in summer and fall and nongame species important in winter in Flathead Lake. May etal. (1988) found rough fishtobethe most importantfishspecies taken in Hungry Horse Reservoir. Carlander (1969) cited several examples of bull trout feeding on sockeye and kokanee salmon

Burbot

Food habits for burbot were determined by analyzing stomachs from 69 specimens captured in Libby Reservoir from 1983 through 1987. Like bull trout, fishspecies were the most important food Source overall for burbot in Libby Reservoir (Table 43). At least nine species of fish were found in stomachs ofburbotincluding one instance of cannibalism. Larval dipterans were also found to be important

The bottom-dwelling organisms utilized by burbotattestto their primarily benthic lifestyle. During fall and winter months largescale suckers were the most important fish prey, and dipteranlarvae were an important food item during all months, especially in fall.

During spring, yellow perch replaced suckers as the most important food source for burbot. This shift in diet is likely because of their proximity to each other in the spring. Yellow perch spawn in sandy areas in the spring (April - June) when vegetation is scarce (Brown 1971, Scott and Crossman 1975). During that time, yellow perch are likely concentrated in several areas in the reservoir, especially in the Rexford area. This is corroborated by the sinkinggillnetrecords, shown previously. The result is a species of fish preferred by burbot (Muth 1973, Scott and Crossman 1975). Yellow perch will likely become increasingly important to burbot if their densities increase.

Other Fishes

Food habits for other fishes captured in Libby Reservoir from 1983 through 1987 are presented in Table 44. Species of greatest interest are northern squawfish, peamouth chubs, and largescale suckers. These are the most likely species to interact with game species because oftheir highdensities in the reservoir and food habits which are similar to those of game species.

Northern squawfish food habits were obtained from spring through fall during the study period. In all seasons, fish were collectively the most important food source for squawfish (Table 45), comprising no less than 90 percent of the total biomass ingested.

 $[\]underline{a}/$ NSQ=northern squawfish, CSU=largescale sucker, CRC=peamouth chub.

It was impossible to assess specific food habits of northern squawfish from Libby Reservoir because of the high percent of empty stomachs (47 percent) and the advanced state of digestion in all but two of the stomach samples. Other authors (Carlander 1969, Brown 1971, Gray et al. 1982, and May et al. 1988) noted the potential for predation by northern squawfish on young salmonids.

Peamouth chubs were consistent in their choice of <u>Daphnia</u> (mean length = 1.70 mm) as a primary food source. Index of Relative Importance values were greater than 65 in all seasons except winter when unidentified fish species were most important. We found no literature to suggest that piscivory might be common to peamouths, but Brown (1971) suggested peamouths may occassionally feed on small fish. Aquatic, and to a lesser extent terrestrial, invertebrates comprised the majority of the remaining prey consumed by peamouth chubs in Libby Reservoir.

It was important to analyze food habits of largescale suckers because of their relatively high utilization of <u>Daphnia</u>. <u>Daphnia</u> was the most important food source for largescale suckers in all seasons in which they were captured. Zooplankton collectively comprised an IRI value of 76 throughout the study period and values were ashighas 89 during the spring season.

Shoener Overlap Index

The Shoener index of dietary overlap was determined for all species of fish that were collected for food habits analysis in Libby Reservoir during the study period. The purpose of the index was to show possible interspecific competitive relationships or community structures. Some ambiguities have been related to combinations of diet measures and dietary overlap indices (Wallace 1981). For this reason, the Shoener index was based on average weights of food items found in the stomachs. This combination probably more closely parallels caloric intake of each food item.

Because of the wide variety of prey preferences for fish in Libby Reservoir, and probability of low index values for some food items, specimens were separated into two groups. The first group contained those fish that were considered to be primarily non-piscivorous based on initial analysis of stomach samples and the work of several other researchers (Carlander 1969, Brown 1971, Scott and Crossman 1973). Group two included all species that were foundtohave fish in any stomachs.

Very little overlap occurred among the non-piscivorous fish (Table 46). Overlap index values ranged from a low of 0.11 between redside shiners and large-scale suckers to a high of 0.95 between mountain whitefish and large-scale suckers. With respect to game species, kokanee and mountain whitefish were the only two species to show ahighindexvalue (0.90). Inaddition, these two species overlapped considerably with large-scale suckers (0.93 and 0.95 for kokanee and mountain whitefish, respectively). The most common food item for all these species was zooplankton.

Table 46. Shoener index values of dietary overlap for eight species of fish considered to be primarily non-piscivorous from Libby Reservoir, 1983 through 1987.

	Trtª/	Csu	YP	Rss	Crc	Mwf	Fsu
Kok	0.19	0.93	0.13	0.05	0.53	0.90	0.24
Trt		0.25	0.26	0.36	0.43	0.31	0.53
Csu			0.20	0.11	0.54	0.95	0.31
YP				0.07	0.21	0.18	0.27
RSS					0.15	0.13	0.76
Crc						0.56	0.35
Mwf							0.32

Kok = kokanee, Trt = Oncorhynchus trout species, Csu = largescale suckers, Yp = yellow perch, Rss = redside shiners, Crc = Peamouth Chubs, Mwf = mountain whitefish, Fsu = long-nose suckers.

Kokanee, mountain whitefish, and largescale suckers consumed zooplankton as 99.1, 86.4, and 92.5 percent, respectively, of their total biomass intake (Table 47). Daphnia were the most important zooplankton taken by each of the fish species. Both percent of total weight and mean lengths of Daphnia ingestedwere similar for kokanee and mountain whitefish. The percent weight of Daphnia ingestedwaslower for largescale suckers, although the mean lengths of Daphnia found in their stomachs were similar

The high Shoener index values, similar percent biomasses, and mean lengths of <u>Daphnia</u> in the stomachs of the three species suggest a potential for interspecific competition. Kokanee are well known for their preference of cladocerans as a food source (Collins 1971, Rieman and Bowler1980, Leathe and Graham 1981). Moutain whitefish also prey heavily on crustacean zooplankton (Scott and Crossman 1973, May et al. 1988). In addition, largescale suckers of all sizes, especially juveniles, are known to feed heavily on zooplankton and also may feed on kokanee eggs (Carlander 1969, Brown 1971, Scott and Crossman 1973).

Many dissimilarities exist among the three species that may suggest little competition in Libby Reservoir. Largescale suckers commonly occupy areas close to the substrate and near shore as do mountain whitefish (Scott and Crossman 1973, and section on tertiary production in this report), while gillnetting in Libby Reservoir has shown that kokanee are primarily limnetic. Largescale suckers arealsodifferentfromthe other species in that they feed heavily on the copepod Cyclops in Libby Reservoir.

Godfrey (1955) found that mountain whitefish fed on limnetic plankton mostly when bottom organisms were scarce and that in those instances, whitefish were commonly at low population densities. Based on netting data, whitefish densities also appear to be low in Libby Reservoir. These different characteristics of the three species suggesthatthereis some spatial separation and feeding mechanism differences that probably keep the three species from competing directly with each other.

Although the Shoener index for Oncorhynchus trout and kokanee was relatively low (0.19) when the entire year was considered, there was some overlap seasonally. For mostoftheyear, trout and kokanee showed little diet overlap (Table 48). During spring and summer, trout fed more on terrestrial and aquatic invertebrates than did kokanee. In the fall months, fish species (mostly peamouth chubs, redside shiners and northern squawfish) also became important in the diet of trout. During this same time, kokanee fedprimarilyon zooplankton.

An overlap index value of 0.85 for trout and kokanee occurred in the winter months and involved primarily zooplankton. However, intense competition probably did not occur between trout and kokanee for the following reasons: (1) utilization of zooplankton by both species may have caused the index to be artificially high because of the numeric parameter; (2) mean lengths of <u>Daphnia</u> ingested by trout were considerablygreaterthanthosetakenby

Table 47. Percent of biomass and mean lengths (mm) of zooplankton types ingested by three species of fish in Libby Reservoir, 1983 through 1987.

kokanee (1.70 mm and1.48 mm, respectively): and (3) alternative food items appeared to be species specific. Trout continued to feed on aquatic, and to a lesser extent terrestrial, invertebrates while kokanee utilized <u>Diaptomus</u> as an important secondary food source.

Many of the fish species from Libby Reservoir that showed piscivorous tendencies were found to have high Shoener index values (Table 49). High overlap values were seen among bull trout, burbot, northern squawfish, and yellow perch. The combined Oncorhynchus trout species showed little diet werlap with any of the other piscivorous species.

Because of the amount of digestionthathad occurred in the stomachsofmostpiscivorousspecies, directcomparisonswereonly possible between bull trout and burbot. Both species preyed on all of the potential forage fish in the reservoir, although proportions of prey consumed were different (Table 50). Bull trout fed on ten species of fish but concentrated on four. The most important prey for bull trout -- in decreasing order of percent biomass -- were kokanee, largescale suckers, trout species, and peamouth chubs. Burbot concentrated on three forage fish species and the order of importance in terms of biomass was largescale suckers, yellow perch, and peamouth chubs.

These differences in prey species suggest differences in feeding strategies between bull trout and burbot. Burbottendto be bottom dwellers and opportunistic (Scott and Crossman 1973, Muth 1973). Iargescale suckers and yellow perch also tend to be bottom dwellers, especially the suckers. In contrast, bull trout in Libby Reservoir are commonly found in open water during most of the year and around the shoreline during summer and fall when they begin spawning movement. This islikelythe reason why kokanee and trout species make up almost one-half of the total biomass eaten by bull trout.

As discussed above, poor stomach samples made it impossible to determine any specific correlations between mostpiscivores and the prey species they consumed. Although May et al. (1988) also found a high Shoener index value for bull trout and northern squawfish, they considered competition unlikely. With respect to Libby Reservoir, continued examination of piscivore stomachs 1s needed to more fully understand their food and feeding habits. This is especially true with the recent introduction of another potential predator, the Kamloops rainbow trout.

MICRANT TRAPPING IN YOUNG CREEK

Introduction

Young Creek, tributary to Libby Reservoir, is situated 5 km south of the Montana-British Columbia border, and drains a 120 sq km basin of the Purcell Mountains. The stream is 17 km long, and median annual low and high flows range from 5 to 100 cfs,

Table 49. Shoener index values of dietary overlap for five species of fish that utilized fish as a food source from Libby Reservoir, 1983 through 1987.

	Burbot	Trout species	Northern squawfish	Yellow perch
Bull trout	0. 99	0.30	0.98	0.84
Burbot		0.17	0.98	0.85

respectively. Young Creek has been used as a test stream for evaluating the feasibility of establishing spawning runs of westslope cutthroat trout in tributaries to the reservoir. Management activities in Young Creek have included removal of migration barriers, chemical treatment of 11 km of the headwaters with rotenone, and annual imprint plantings of about 50,000 young-of-the-year westslope cutthroattroutper 300 m of stream from 1970 to 1975.

Methods

An upstream box trap and a downstream Wolf-type trap (Huston et al. 1984) were operated in Young Creekbetween 1970 and 1987. The trap structure is located about 100 m upstream from the full pool elevation of Libby Reservoir. The dates of operation varied between years. During certain periods workers were on site 24 hoursadaytoensure that debris and peak flows did not interfere with trapping efficiency.

Results and Discussion

Migratory trout have been captured inbi-directionaltraps in Young Creek in all years since 1970, except for 1980 and 1981. Results of the trapping are summarized in Table 51. The duration of upstream and downtream trapping periods, and the effort expended in trapping each year were not equal. This disparity precludes standardizing total catches between years. Comparisons made on the basis of daily catch rates are also inappropriate since run strength on a given day inaspawning periodvaries with discharge and temperature.

Migrants caught in the first three years of trapping in 1970, 1971, and 1972, were considered to be residents of the Kootenai River. The increases in adult captures from 1970 to 1972 were probably the result of the removal of migration barriers in Young Creek. None of the fish caught in those three years were allowed to pass beyond the trap. The post-1973 migrants were therefore considered to be largely the products of reservoir and Young Creek plantings.

Huston et al. (1984) estimated the one year survival of young-of-the year cutthroat planted in fall 1972 to be about 42 percent. Results of the plantings are evident in the period from 1973 to 1977 in which the numbers of adult cutthroat captures increased from 102 to 679. The captures in 1978 are not considered representative since trapping was terminated before the spawning run normally begins. The trap was removed in 1978 on May 3, and Huston et al. (1984) stated that the run normally occurs throughout the month of May.

Captures in 1979, 1980, 1983, and 1984 were fairly similar, but roughly half the size of the 1976 and 1977 peak. In the years 1985, 1986, and 1987, there were substantial reductions in adult captures. The number of adults captured in 1987 wasthelowest since 1972.

1987	48 (4/28- 6/15) (5/18- 7/16)	56	33	596

Huston et al. (1984) offer the following explanations for the declining spawning populations in Young Creek: (1) increased angler harvest in Young Creek; (2) deterioration of habitat quality in Young Creek from human development and forest management; (3) cessation of imprint planting in Young Creek; and (4) decreased survival of Young Creek cutthroat in the reservoir.

An additional factor may be the mortality and stress that the long-term trapping program itself imposes on the Young Creek spawning population.

RECOMMENDATIONS

- The effects of the deep drawdown in 1988 and 1989 should be thoroughly researched to document its impactonthereservoir fishery.
- 2. Continue to develop and implement strategies to evaluate and refine the model from 1988 through 1992. This will increase the predictive capability and therefore usefulness of the model.
- 3. Refine the annualhydroacoustic estimate through the use of dual-beam echo-sounding equipment.
- 4. Emphasize data collection to address system variables and trophic level interactions. An example of a critical variable not fully researched in Libby Reservoir is the reservoir hydraulics. This variable directly affects primary production and may influence all trophic levels even fish distribution and predation rates. An example of trophic level interactions that may be critical in Libby reservoir are the interplay between Daphnia diel vertical distribution, kokanee activity patterns and reservoir hydraulics. Itwouldalsobedesirable to more closely quantify surface insect deposition using floating insect traps.
- 5. Emphasize collection of data on peamouth age, growth, food habits and interactions with other fish species. The peamouth is numerically the mostimportantfish in Libby Reservoir and its numbers are apparently increasing. The status of the Kamloops rainbow trout, bull trout and northern squawfish and their feeding habits should continue to be monitored as closely as possible.
- 6. Evaluate the timing and significance of fish entrainment through the Libby Dam turbines. This information can be used tolinkthe reservoir and river fishery.
- 7. The effects of dam operation the Kootenai Riverfisheryshould be investigated beginning in 1990. Once effects are determined, themodelcanbeusedto evaluate and recommend dam operations that will optimize the river and reservoir fishery. Investigations on the Kootenai River should include:

 (a) Instream Flow Incremental Methodology (IFIM) work on the river channel: (b) habitat suitability investigations on rainbow, bull trout, mountain whitefish and burbot; (c) creel surveys; and (d) investigation on the rate of delta formation at the mouth of tributaries. This work will address program measures 903(b)(1,3), 903(a)(6), 903(d) and 903(e)7 in the 1987 Fish and Wildlife program.

APPENDIX A Figures Al through A7

Hydrologic characteristics of Libby Reservoir, 1983 through 1987.

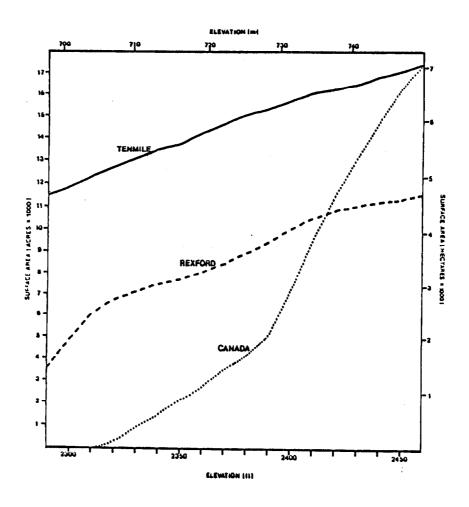

Figure A1. Relationship of Libby Reservoir surface elevation (feet) to area (mega acre feet).

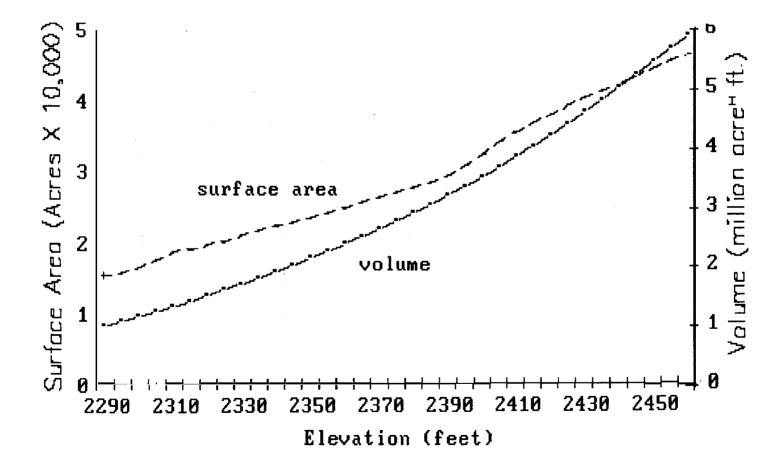

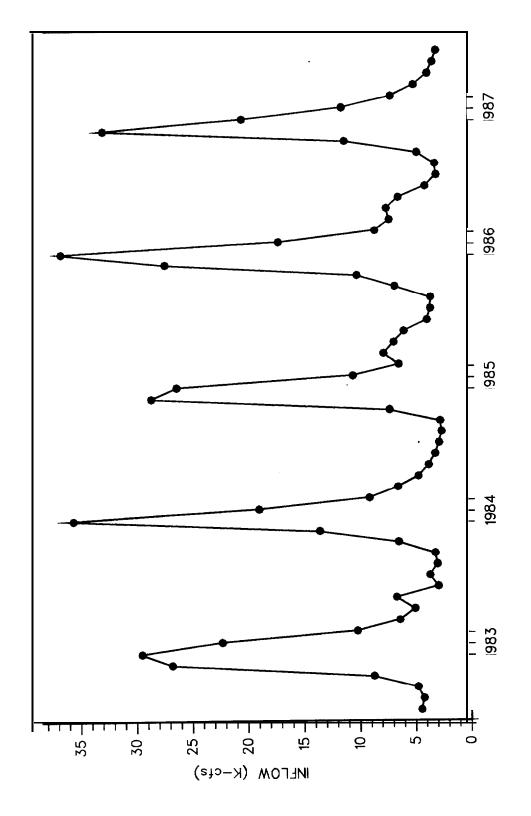

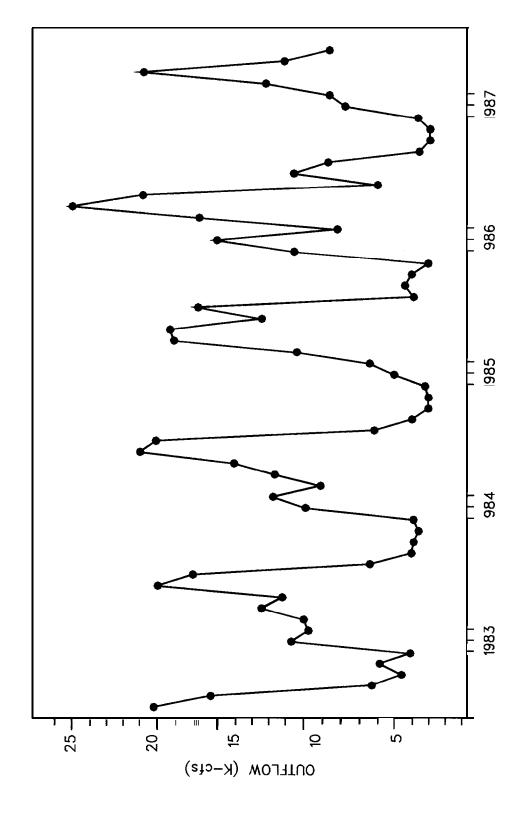

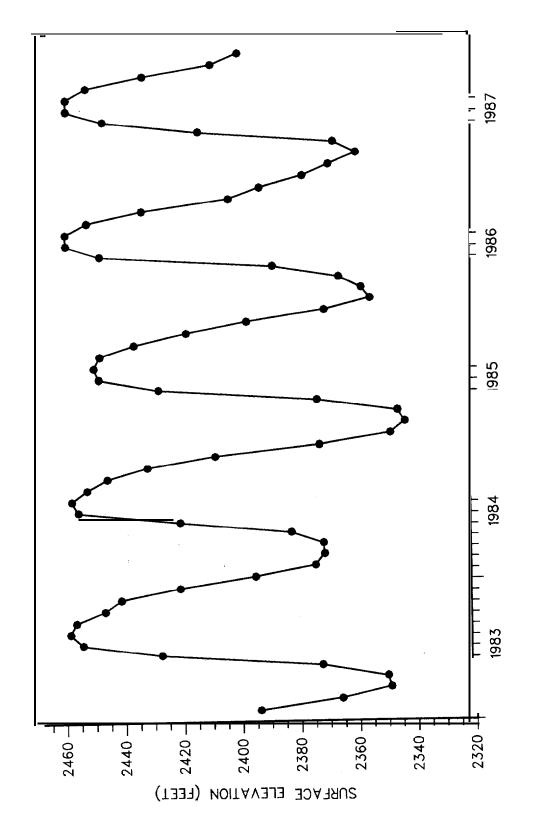

Figure A2. Relationship of Libby Reservoir surface elevation (feet) to volume (million acre-ft) and surface area (acres x 10,000).

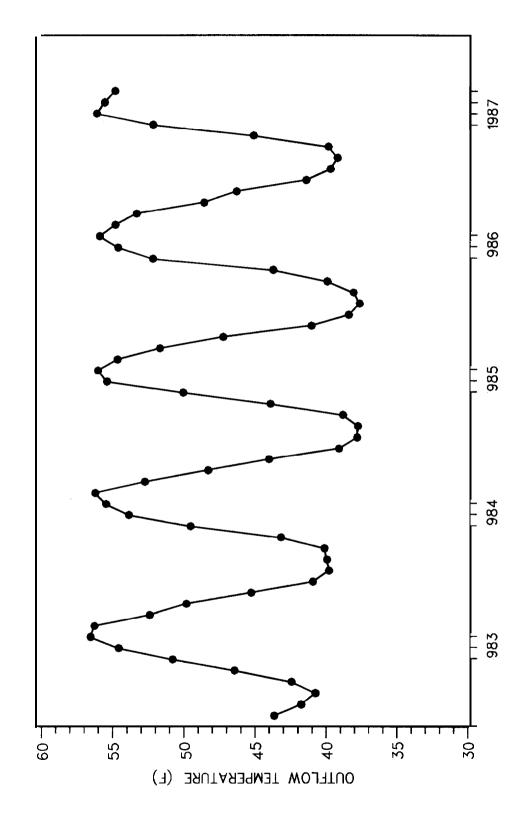

Mean monthly inflow to Libby Reservoir, 1983 through 1987. Figure A3

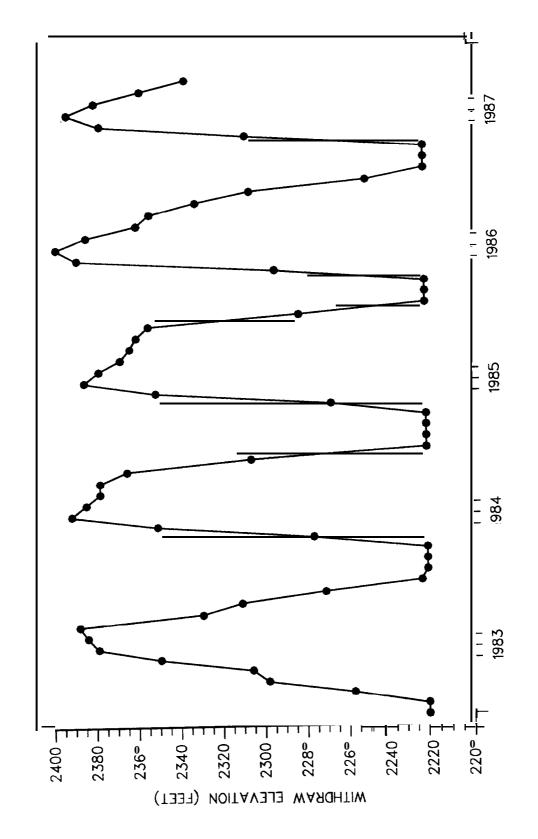

Mean monthly outflow from Libby Dam. 1983 through 1987 Figure A4

Mean monthly surface elevations (feet above ms1) for Libby Reservoir, 1983 through 1987. Figure A5.

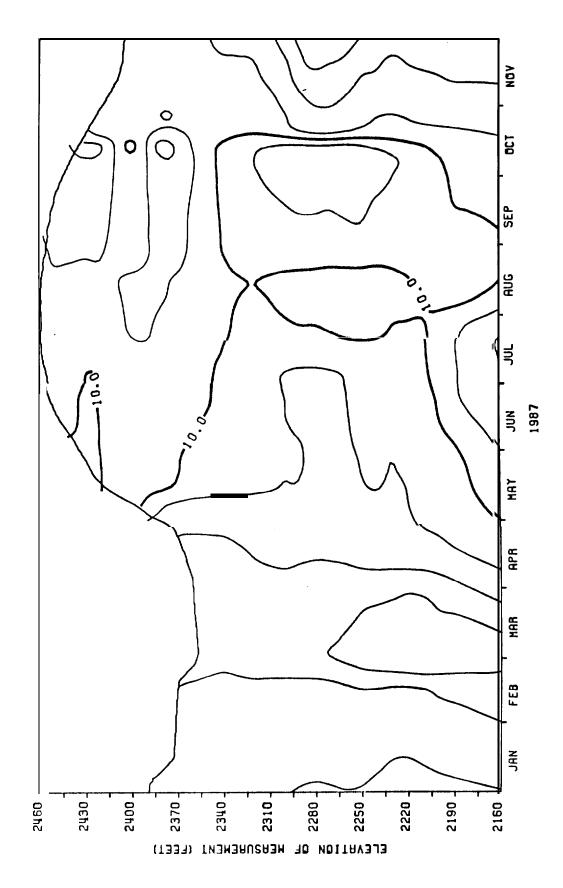

Mean monthly temperature of discharge at Libby Dam, 1983 through 1987. Figure A6.

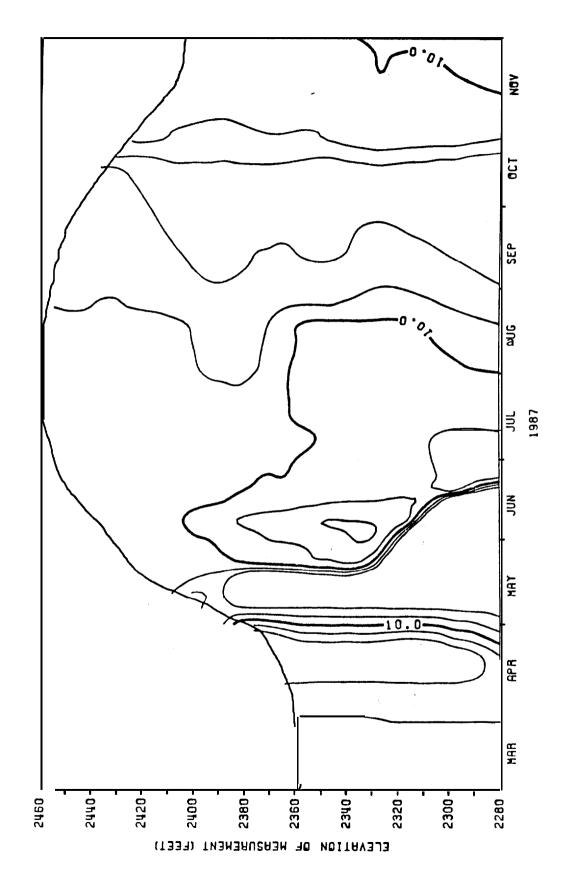

Data Depth of discharge withdrawal at Libby Dam, 1983 through 1987 provided by Army Corps of Engineers. Figure A7.

APPENDIX B Figures B1 through B12

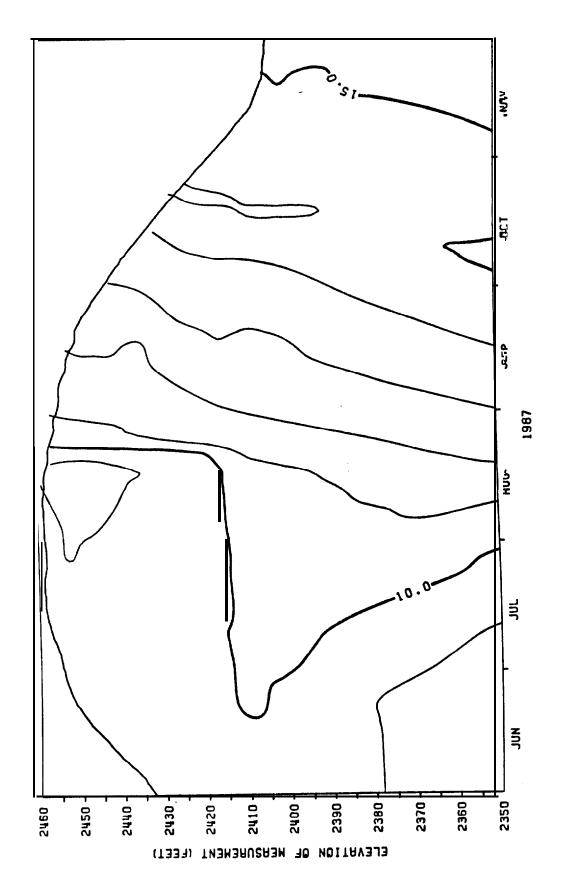

Water quality parameters for three study areas of Libby Reservoir, 1987.

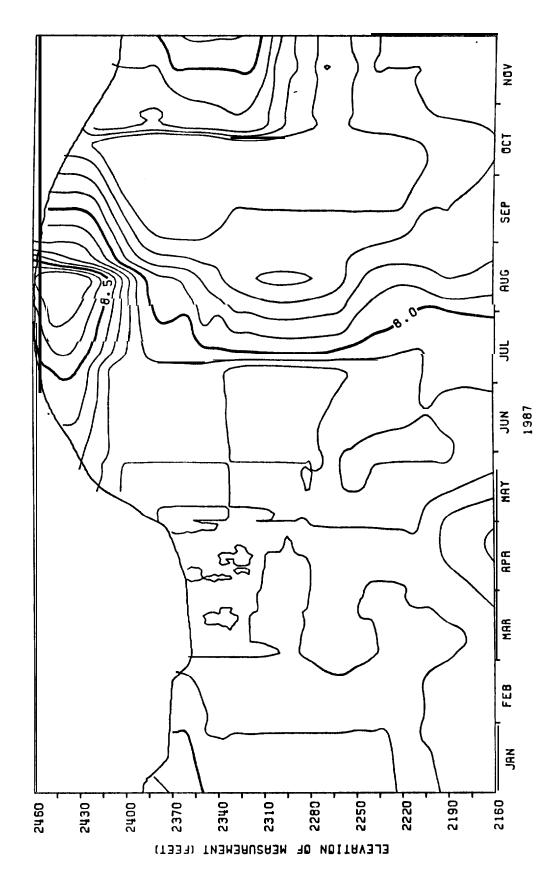

Dissolved oxygen content *mg/1) at reservoir elevation and depth in the Tenmile area of Libby Reservoir, 1987. Figure B1.

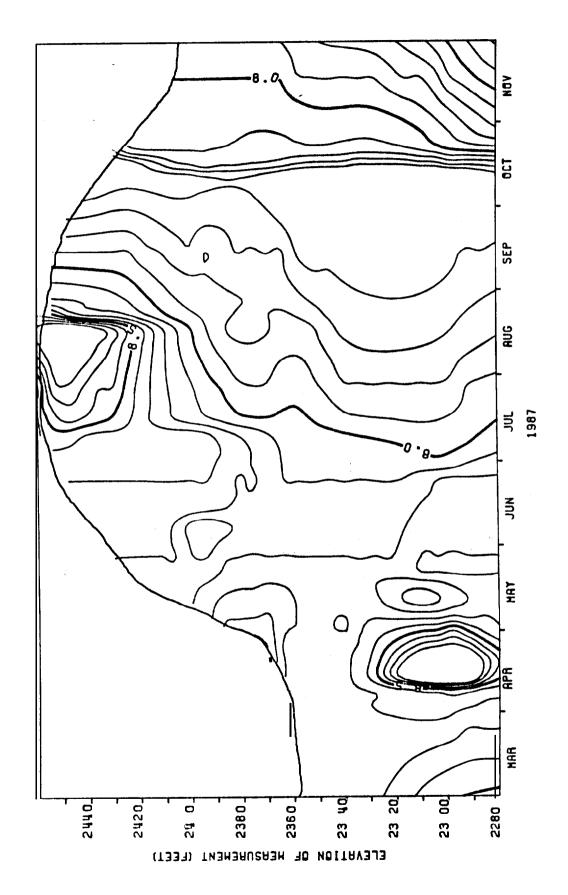

Dissolved oxygen content (mg/1) at reservoir elevation and depth in the Rexford area of Libby Reservoir, 1987. Figure B2.

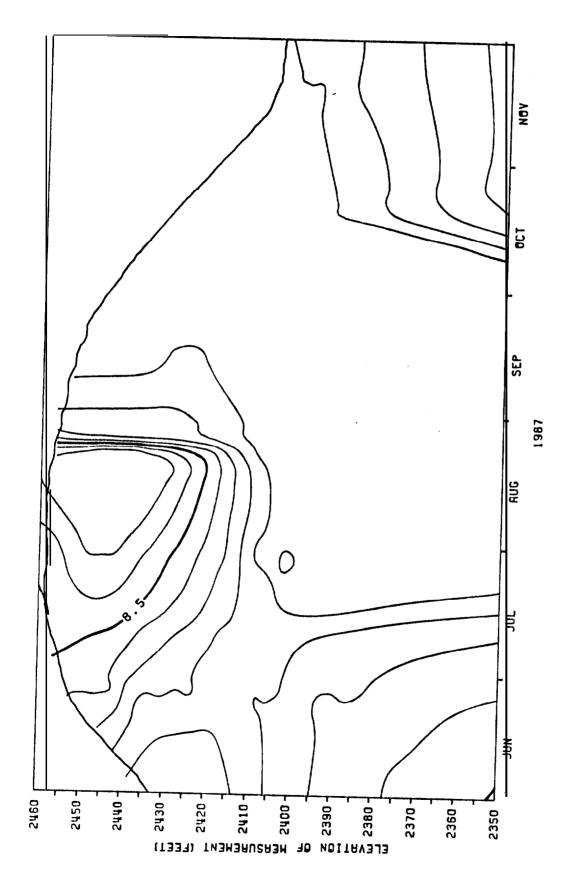

Dissolved exygen centent (mg/1) at reservoir elevation. and depth in the Canada area of Libby Reservoir, 1987. Figure B3.

urements of pH (0.1) at reservoir elevation an $^{\omega}$ epth in the ile area of Libby Reservoir. 1987. **M**e ∃ Figure B4.

Measurements of pH (0.1) at reservoir elevation and depth in the Rexford area of Libby Reservoir, 1987. Figure B5.

Measurements of pH (0.1) at reservoir elevation and depth in the Canada area of Libby Reservoir, 1987. Figure B6

Figure B7. Water temperature profiles (2°C) at reservoir elevations in the Tenmile area of Libby Reservoir, 1987.

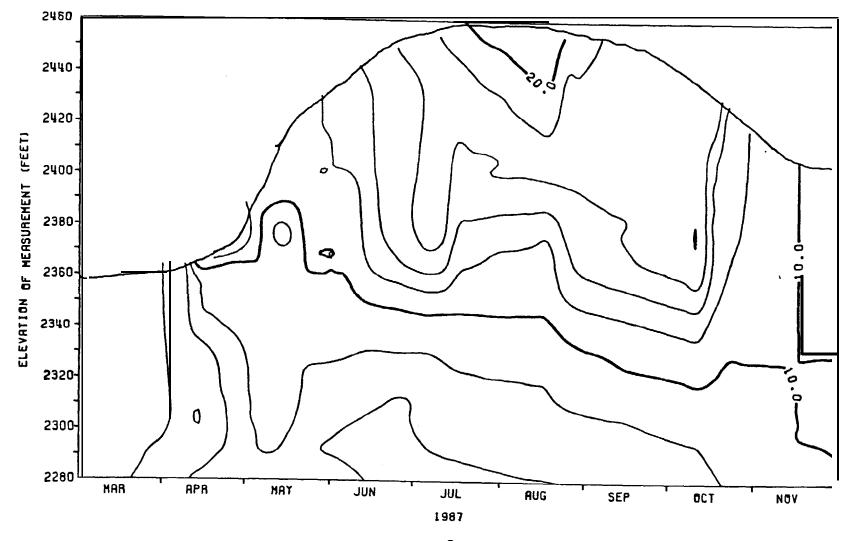

Figure B8. Water temperature profiles (2°C) at reservoir elevations in the Rexford area of Libby Reservoir, 1987.

Figure B9. Water temperature profiles (2°C) at reservoir elevations in the Tenmile area of Libby Reservoir, 1987.

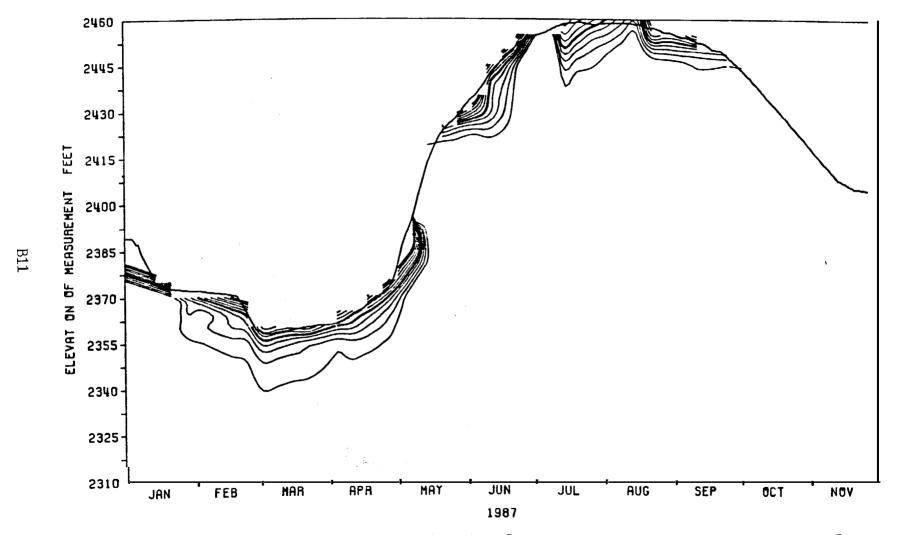

Figure B10. Profiles of light extinction for elevation in the Tenmile area of Libby Reservoir, 1987. Each line represents 10 percent extinction.

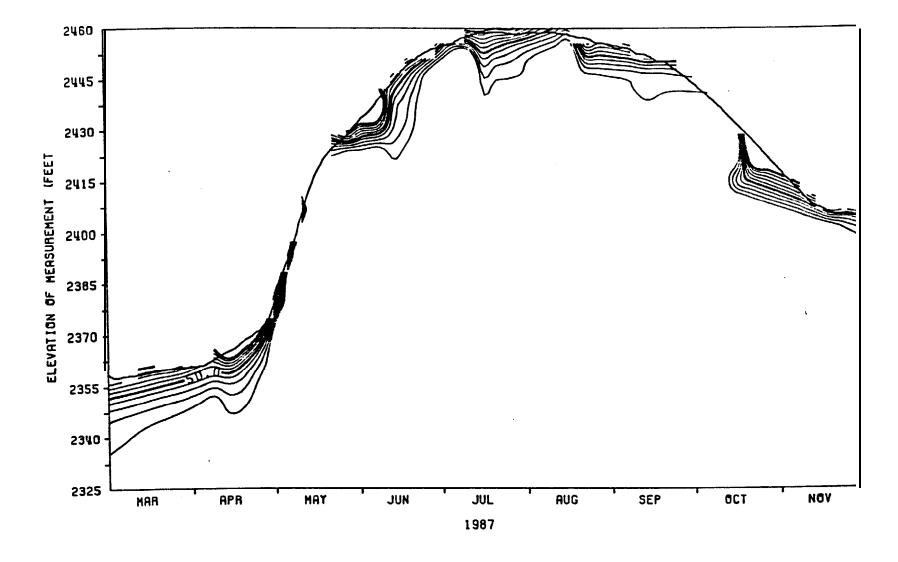

Figure B11. Profiles of light extinction for reservoir elevations in the Rexford area of Libby Reservoir, 1987. Each line represent 10 percent extinction.

Figure B12. Profiles of light extinction for reservoir elevations in the Canada area of Libby Reservoir, 1987. Each line represents 10 percent extinction.

APPENDIX C Tables C1 through C36

Monthly densities and biomasses of terrestrial and aquatic invertebrates in the three study areas of Libby Reservoir, 1983 through 1987.

Table Cl. Surface invertebrate density in no./ha. (standard deviation) by Order, in the Termile area of Libby Reservoir during 1983.

APPENDIX E Figures E1 and E2

Distribution of the percent total <u>Daphnia</u> by size class in Libby Reservoir, 1983 through 1987.

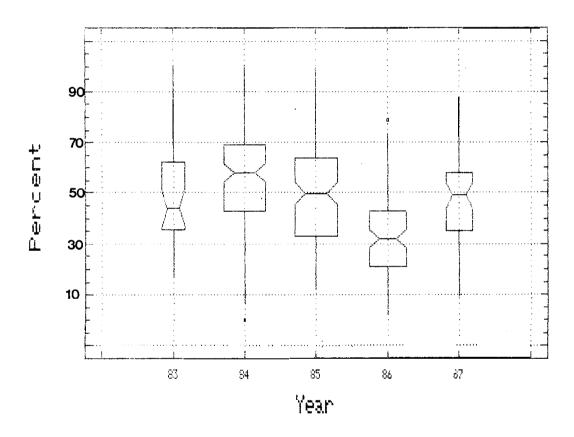

Figure El. Distribution of the percent total <u>Daphnia</u> in the 0.50 to 0.99 mm size class for 1983 to 1987, Libby Reservoir. Horizontal lines indicate median values; boxes enclose the middle 50 percent of the values; solid vertical lines extend to 1.5 times the interquartile range; outlier values beyond solid line are indicated as dots; notches in box indicate 95 percent confidence level of median value; width of box is proportional to the square root of the number of observations in the sample.

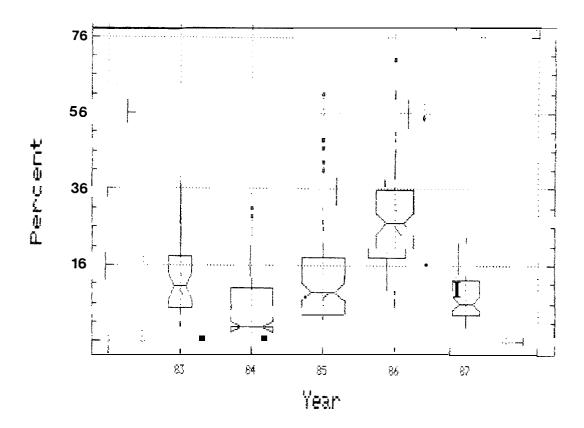

Figure E2. Distribution of the percent total Daphnia in the 1.5 mm to 1.9 mm size class for 1983 to 1987, Libby Reservoir. Horizontal lines indicate median values; boxes enclose the middle 50 percent of the values; solid vertical lines extend to 1.5 times the interquartile range; outlier values beyond solid line are indicated as dots; notches in box indicate 95 percent confidence level of median value; width of box is proportional to the square root of the number of observations in the sample.

APPENDIX F

Tables F1 through F15.

Monthly and yearly average densities and yearly average lengths of zooplankton samples from Schindler traps in three areas of Libby Reservoir,

1983 through 1987.

Table F1. Monthly average density (N/I) of <u>Dephnia</u> in the Termile area of Libby Reservoir at depths, 1983 through 1987. Values in parentheses are the standard deviations. For entire population: \bar{x} =1.8282, SD=2.9864, N=369.
